A Case of Papular Erythema following Vaccination.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, JANUARY 4, 1896. NO. 1.

ORIGINAL ARTICLES.

A CASE OF PAPULAR ERYTHEMA FOLLOWING VACCINATION.

BY GEORGE HENRY FOX, M.D.,
OF NEW YORK;
CLINICAL PROFESSOR DISEASES OF THE SKIN, COLLEGE OF PHYSICIANS AND SURGEONS.

IN the simple operation of vaccination it is possible to convey syphilis, leprosy, septicæmia, and perhaps tuberculosis, if due precaution is omitted. But the well-authenticated instances where even so common a disease as syphilis has been conveyed through vaccination are very few. The many evil results which are popularly ascribed to "bad virus" are due either to injury or irritation of the vaccinated part, to the accidental infection of the pustule, or to a personal idiosyncrasy which leads to the development of a rash, such as sometimes follows the ingestion of certain drugs or articles of food.

Irritation of the vaccine vesicle may lead to severe dermatitis, cellulitis, and subsequent ulceration. Infection of the vesicle or pustule by atmospheric germs may induce erysipelas, furunculi, and contagious impetigo, which latter affection may be inoculated elsewhere by means of the finger-nails, and give rise to a pustular or crusted eruption which is very apt to be mistaken for "generalized vaccinia."

The systemic reaction after vaccination may induce eruptions of varying types. These may appear before the development of the vesicle, but are most frequently met with when this is at its height. They may be erythematous, urticarial, purpuric, and even vesicular or bullous in character, but present no specific features which would indicate their vaccinal origin. These eruptions may depend upon some abnormal condition of the patient, in which case the vaccination cannot be regarded as the prime cause of the rash, inasmuch as it merely evokes an eruption which was already latent and which might have appeared spontaneously or from any one of a variety of causes. Frequently, however, the vaccinated subject is in normal health, and the vaccinal eruption, like a drug rash, can only be attributed to idiosyncrasy.

A not uncommon form of erythemato-papular eruption is illustrated in the following case and by the accompanying chromo-lithograph:

In November last I was asked to see a two-year-old child under the care of Dr. Pierson, of Morristown, N. J. The arm presented a well-developed vaccine pustule, drying into a blackish crust (ninth day). Around this were considerable redness and swelling, although there was no indication that the vaccine lesion had been injured or irritated in any way. The face was somewhat swollen, and spotted with a few irregular erythematous patches. The trunk was nearly covered with a bright red erythemato-papular eruption, which occasioned the infant considerable distress. The lesions consisted of pin-head-sized, follicular papules, mostly aggregated in small, rounded patches and confluent upon the middle of the back, where the skin appeared red and smooth. The papules were numerous upon the palms, and there were a few upon the soles. Upon the extremities (except near the vaccine pustule) the eruption was by no means as copious as upon the trunk.

The eruption had appeared early in the morning of the preceding day (a week after vaccination), upon the vaccinated arm. In the evening it had developed upon the trunk. After a very restless night the eruption had become quite general, as already described. At this stage the photograph was taken. During this second day of the eruption the patches upon the trunk became smoother and less angry in hue, although they had increased somewhat upon the arms and legs. The skin was still hot and itchy, gentle rubbing of the back proving very grateful to the little sufferer. The temperature marked 103½°. The treatment consisted in a laxative dose of calomel and the application of a lotion containing oxide of zinc in lime water.

On the following morning the eruption was much smoother and paler. Some of the small discoid patches on the trunk presented a bright peripheral ring with a dull-red or livid centre. Nearly the whole surface of the child's body was involved by the eruption, and the small areas of normal skin presented a strong contrast with the affected portion. The eruption faded rapidly, and the drying of the vaccine crust proceeded as though no rash had occurred.

VAGINAL VERSUS ABDOMINAL SECTION IN DISEASES OF THE FEMALE PELVIC ORGANS.

BY WILLIAM M. POLK, M.D., LL.D.,
OF NEW YORK;
PROFESSOR OF OBSTETRICS AND GYNECOLOGY, MEDICAL DEPARTMENT, UNIVERSITY OF THE CITY OF NEW YORK.

THE rapid evolution of the surgery of the female pelvic organs is one of the great things of this part of our century. Question succeeded question in quick succession until many felt that the end had been reached, and all that remained was the task of perfecting what had been developed. Hardly had we settled down in complacent contemplation of our results with the Trendelenburg posture when we were rudely shaken by this cry of the "vaginal method." Turn from it as often as we may, it yet sings in our ears, and will not be silenced. Intrench ourselves behind a resolution to see in it nothing of good for our patients; view it as a new hobby upon which those of shallow judgment are riding to notoriety, not to honest repute; decry it in all and every way, and it will not down. This is proven by the experience of the past year in this country alone, not to mention what has occurred abroad.

We are to be congratulated that such has been the result of the agitation, for it shows the virility of the subject, and proves that there is a great deal in it for our consideration. As a matter of fact, it is probably the last great question in the surgery of the female pelvis, and deserves to be treated as such by our best men.

Vaginal section has already been injured by exaggerated claims in its behalf. It is folly to talk of driving abdominal section from the field with it, for the reason that conditions will always occur which can be so much better met by the former that no good surgeon would decline to employ it. I think also that the vaginal section will always serve as subordinate to the abdominal, even though it diminish the frequency of the latter one half or two-thirds. This belief is based upon the acknowledgment that abdominal section must sometimes be used to complete the work begun through the vagina. In other words, there are cases supposedly entirely amenable to vaginal section, but which demand, as the operation proceeds, a better operative field, which can only be had by combined section. This single admission shows the interdependence of the methods, and suggests that wherever the boundary between them be drawn it must be made movable; nothing hard and fast can be tolerated.

It is interesting to recall that vaginal section not so long ago held the vantage-ground in this territory, and was driven out except in the case of carcinoma because of its poor results. This was due to its faulty technique in part, and in part to a lack of familiarity with the actual condition which could be present with a diseased uterus and appendages. Through abdominal section it has now informed itself and perfected its technique, and again comes forward for recognition.

Our attitude in this contention can be best expressed by assuming one hundred as the total of all cases of disease in question now recognized as suitable for section. One year ago I thought this could be divided equally between the vaginal and the abdominal. I now think seventy-five can be assigned to vaginal section, leaving twenty-five to be treated by the abdominal.

As the indications for or against depend largely upon the dimension of the diseased area or growth, one must admit that the earlier the operation is done, the greater the chance for vaginal section. So, assuming that one could observe all cases of uterine and adnexal disease from the outset, it is probable that the ratio would be still further increased in favor of the vaginal route.

Beginning this work at Bellevue Hospital in February, 1892, we have now performed seventy-two vaginal sections, with three deaths, covering every species of disorder for which it has been advocated. This ignores vaginal hysterectomies for carcinoma done in the years prior to 1892, for we wish to eliminate from this discussion as much old timber as possible. What we have to say is based upon our own work; work in no way original, however, although it has not been checked by the observations of others, for we tried to approach the subject with an unbiased mind and aimed at independent work, so that when informed from personal experience we could compare conclusions with cotemporaries and with those who had preceded us. It is evident from this statement that we are prepared to modify our conclusions when it can be shown that they are not properly based.

With this understood, we now submit a statement of conditions favorable, on the one hand, to vaginal section, and, on the other, to abdominal section.

Exploratory incisions. There are certain obscure conditions of the appendages of the uterus and sigmoid flexure in which exploratory abdominal section has become a recognized operation. Accurate vaginal and rectal bimanual palpation under ether is insufficient to discover enough gross lesions to account for symptoms. Direct palpation or inspection is needed for diagnosis. For instance:

CASE I.—A young married woman, the victim of constant pelvic pain and dysmenorrhœa, came to the writer for operation, having been told by competent authority that nothing short of removal of the ovaries would effect a cure. The pain was referred to the region of the left appendages. Examination without ether revealed what appeared to

be a thickening of the tissue at the base of the left broad ligament, the region being very tender. Under ether the thickening was less marked, but there appeared a sufficient contrast with the same region upon the right to leave the diagnosis in doubt, especially in view of the constant, long-continued complaint of pain. A free incision was made into the cul-de-sac. A careful and thorough palpation of all the structures in the pelvis was made with two fingers, and nothing abnormal could be found. The appendages were drawn into the vagina, and inspection, as well as palpation, showed that they were normal. The patient was up in a week, and, as so often happens after an exploratory incision in such cases, was cured by the operation.

Or take another instance (Case II.). Following curettage and trachelorrhaphy an inflammatory mass developed in the outer upper region of the right broad ligament. Supposing it to be salpingitis plus ovaritis, the cul-de-sac was opened with a view to removal or evacuation. To our surprise tube, ovary, and surrounding peritoneal area were normal. But as the swelling was all the more evident it was carefully palpated with a view to operation. The uterus was drawn down by volsella and two fingers were swept over the entire pelvis. First over the posterior surface of uterus, then the anterior, then along the upper border of the broad ligaments, then down into the paravesical fossæ, thence over the bladder, the anterior pelvic, and lastly the posterior pelvic walls. The following abnormality was in this way mapped out. The outer upper region of the right broad ligament, including its line of connection with the pelvic wall, contained a hard mass; between it and the uterus was a distinct sulcus, in which the tissue, though thickened, appeared in fair condition. To the front, the right paravesical fossa was wellnigh obliterated, the outline of the linea terminalis from the attachment of the broad ligament forward to near the symphysis was obscured all by soft swollen tissue, which evidently was nothing more than a collection of pus connected with and springing from the mass in the broad ligament. We were now at liberty to select an exit for the pus. This could be had in two ways. A direct incision above Poupart's ligament, turning up the peritoneum, reaching the pus about the pectineal eminence. Another route, and the one selected, was directly from the vagina. The cul-de-sac was closed; then, in order to reach the pus and at the same time avoid the ureter, an opening was made as in anterior colpotomy; this was extended beneath the peritoneum, upward and outward to the region of induration, whence the pus thus freely escaped.

Displacements fixed by adhesions. From several cases we select one (Case III.) in which the uterus was retroverted, ovaries prolapsed, and both, with the tubes, were bound down by firm and old adhesions. For two years prior to operation the patient had been subjected to vaginal tamponade for the purpose, as was said, of stretching the adhesions, so as to permit the uterus and appendages to be raised by a pessary. The folly of this policy was never better illustrated, for the organs remained, as they always do, in the abnormal position. Free incision of the cul-de-sac gave easy access to the structures. These were readily stripped of their adhesions, and then by means of Alexander's operation they were permanently placed in proper position. Easy and speedy recovery marked this case.

Ovarian tumors. All such tumors small enough to be contained, wholly or in large part, in the pelvic cavity should be removed by vaginal section. Tumors large enough to reach beyond the umbilicus, especially if they are pedunculated and are wholly outside the true pelvis, can be best treated by abdominal section. This observation applies with greatest force to multilocular colloid growths, but even then it is susceptible of modification in favor of vaginal section if it can be shown that both ovaries are hopelessly diseased. Then hysterectomy being permissible, sufficient opening is secured to evacuate properly and withdraw even such colloid growths. If this be true of these latter tumors, it applies with greater force to unilocular cysts with more fluid contents. From this it must appear that while tumors wholly outside the pelvis can be best treated by abdominal section, many of these can be reached by the vagina, provided it be proper to remove the uterus. In these cases it is wise to operate with the hips somewhat raised, else the intestines and omentum will occupy the field, and are apt to cut off the escape of fluid, which then tends to ascend and accumulate just under the abdominal walls.

CASE IV.—An intraligamentous ovarian cyst of the left side, with dimensions about equal to the fœtal head at seven months, was removed per vagina through the cul-de-sac. Some difficulty was experienced in enucleating the sac. This was overcome, however, by opening the anterior fornix, through which the sac was easily removed. Our experience in this case impressed us with the advantages of the anterior over the posterior line of approach in the intraligamentous growths. By this route most of them can be removed without entering the peritoneal cavity. After reaching the under surface of the peritoneum in the utero-vesical fold, it is only necessary to push aside the tissue with the finger, when the wall of the sac contiguous to the lateral uterine wall is easily reached and punctured. Subsequent enucleation can then be readily made. By hugging the uterus well up to the region of the body before attempting puncture of the sac, one easily avoids ureter and bladder. Hemorrhage is readily controlled by forceps.

Case V. *A small pedunculated ovarian cyst (size of fœtal head at term).*—The cyst was adherent to the pelvic floor, was therefore readily reached and quickly removed. All such cases are eminently fitted for the infrapubic operation. Solid or fluid, hard or soft, benign or malignant, the route through the cul-de-sac gives easy access and ready control of each and all.

Case VI. *Extra-uterine pregnancy.*—This was an example of an extra-uterine fœtation, in which incision, evacuation, and drainage brought a speedy cure. Bleeding points were many, but they were secured by forceps, which were left in place forty-eight hours. This is a condition which, prior to rupture, one can always elect to reach by the vagina. The tumor from first to last is well down in the posterior regions of the pelvis, and is easily reached through the posterior vaginal wall. It may be necessary to remove the uterus, however, for without this addition we may have excessive hemorrhage. Still, if one can get hold of the connection of the mass by clamping upon its two sides, outer and inner, bleeding can be stopped. After the placenta is fully formed, the child being alive, the suprapubic route would no doubt be preferable. Touching those cases, whether early or late, in which from antecedent rupture or otherwise the fœtus is dead, the infrapubic route will meet every requirement, as we have then little more than to evacuate and drain.

Inflammation and suppurative disease of the appendages, including tubercular disease. This field is particularly rich in opportunities for vaginal section. In fact, there appears to be no stage which positively contraindicates it. It offers the best means of checking the ravages of acute inflammation, thus tending to the highest kind of conservatism; it affords opportunity for the partial plastic operations upon the adnexæ and uterus, and it gives us the best operation for suppurative disease of these same adnexæ, when their removal is demanded, as in tubercular disease and in the destructive inflammation of both appendages.

It is interesting to note that this class of cases has furnished the battle-ground of this question. But the increasing belief that the uterus must go with the appendages, that hysterectomy in destructive double adnexal disease is required, and, further, that plastic so-called conservative operation upon the uterus and appendages can be done through the vagina bids fair soon to settle the question in favor of vaginal section.

Case VII. *Acute processes.*—This is an instance of acute salpingitis and pelvic peritonitis following abortion at two and one-half months. The uterus was cleansed and packed with sterilized gauze; the cul-de-sac by a free opening evacuated of turbid serum. The inflamed appendages were not disturbed, a loose gauze drain being carried into the cul-de-sac, which was first washed out with sterilized water. Finally, the vagina was loosely packed with gauze. This was removed at the end of forty-eight hours, the final result being all that could be asked.

This case illustrates what will probably be a common application of one step of the infrapubic operation, namely, the incision into the cul-de-sac with a view to drainage. This step appears to promise much in mitigating the damage which befalls the appendages in the face of the inflammations which come to them through those very common causes—abortions and gonorrhœa. The cleansing of the uterus, together with free drainage from the pelvic peritoneal area, seems to be the rational way of treating such cases, but it is a self-evident proposition that to be of service it must be done early.

Case VIII. *Acute puerperal metritis, etc.* In connection with the preceding case the present one illustrates the ease with which one may go to extremes when necessary in puerperal septic cases. A woman was septic five days, the form being sapræmia rather than mere sepsis. In ten minutes the uterus was removed and the operation completed. The relaxed and dilated state of the whole genital tract makes the operation exceptionally easy. From this we infer that all such cases are peculiarly fitted for the infrapubic operation.

Chronic processes. For illustration, a synopsis of three cases is now given.

Case I.—By means of *anterior colpotomy* the uterus was anteverted, the fundus and the appendages were brought through into the vagina. The right appendage was normal, the left diseased. The left was removed. The remaining organs were then returned to the peritoneal cavity. The opening in the peritoneum was closed, that in the vaginal wall left open. The uterus was curetted and packed; patient out of bed in a week.

Case II.—By means of posterior colpotomy an adherent and purulent ovary and tube were discovered on the left side. They were removed, a clamp being used. Upon the right side the appendages, being normal, were not removed. The uterus was treated as in Case I. and the patient did quite as well.

Case III. represented a double ovarian abscess and double pyosalpinx. The pelvis was practically filled with the mass and the associated adhesions. The uterus was first cut out, and then the left and, lastly, the right appendages were removed. The process was tedious, and, owing to the intimate and firm attachment of the rectum, this intestine was torn. No attempt at closure was made, as the opening was small. The recovery was quick, but a fecal fistula remained for two months, when it finally closed spontaneously.

Fibroid disease of the uterus. The tumors when of small size are more amenable to vaginal section than almost any other condition. This has already been well brought out at the Obstetrical Society in this city, to whose proceedings I refer for more specific remarks in this direction.

In brief, it may be said that all fibroid tumors lying chiefly in the pelvis are suitable for morcellation by the vagina, the intraligamentous for instance. Pure myomas and fibro-cystic tumors, even though they extend as high as the umbilicus, may also be brought within the limits of vaginal section, but not so with the hard, pure fibroid growths. It is difficult to fix any limit for these, but in general it may be accepted that where such tumors are wholly above the pelvis and fill the hypogastric region they had better be removed by abdominal section. Especially is this the case if the pelvis is narrow and deep; but we find much encouragement to the removal of these growths by the vagina when we contemplate the remarkable work accomplished for so many years in the removal of submucous fibroids by vaginal morcellation.

Objections. After all has been said it is plain, however, that there are objections to vaginal section which are sufficient to deter many operators from adopting it. Let us see what they are. The conformation of the pelvis does exercise a decided and, it may be, a controlling influence. All deep, narrow pelves render vaginal section difficult, and in the case of partial operations, such as removal of but one appendage, when thickness and rigidity of the pelvic floor, as may be met with in some women, is added, will practically forbid it. In the presence of a male pelvis in a stout woman with a narrow vagina one should be slow to adopt vaginal in preference to abdominal section. In this connection I quote from an article already published in the *American Journal of Obstetrics*, vol. xxxi., No. 2, page 5:

"The anatomical condition which presented to me the greatest difficulty was that found in large women with the male pelvis. The deep pelvis with its comparatively narrow outlet was usually found to contain a uterus with unusually thick and inelastic utero-sacral ligaments. I also found in some of these cases a considerable depth of tissue (fat and connective tissue) in the make-up of the pelvic floor. Douglas's cul-de-sac was deep and narrow, and the lateral fossæ of Douglas were wide and roomy. It is in these lateral fossæ that the diseased appendages commonly rest; under the above conditions it was not always easy to reach and enucleate them and then draw them into the vaginal opening. Such a pelvis, however, would offer no special obstacle if the condition demanded hysterectomy, for then the prior removal of the uterus would give easy access to the appendages, no matter where located within the true pelvis. After such removal the opening at command would be almost equal to the confines of the recent pelvic excavation, and through it, as has been shown here, large pus-tubes and ovarian abscesses could be safely removed. Clearly, then, an element of obstacle in this work is the uterus itself. If the operator planned to remove this organ as a part of his operation, he would have before him no greater procedure than a vaginal hysterectomy, one, too, which was far simpler than the same procedure when executed for carcinoma. A vaginal hysterectomy for cancer generally meant as much encroachment upon tissues and organs about the uterus as was compatible not so much with the integrity of adjacent structure as with the life of the patient. A vaginal hysterectomy for inflammatory disease of the uterus and appendages and for fibroid disease meant, on the contrary, freedom to hug the diseased tissue as closely as possible. In the one, bladder, ureters, and rectum might be in constant danger; in the other they are excluded from the field with the utmost ease. No adventitious guides or guards are needed; such things become, in fact, a hindrance rather than an aid.

"Referring again to partial operations upon the female pelvic organs, such as salpingotomy, oöphorectomy, resection of ovaries, excision of pyosalpinx, etc., I find that the thinner the subject and the more shallow and roomy the pelvis the greater the ease of procedure. Another factor likewise exists, as already mentioned, in the make up of the pelvic floor. The thinner this is the easier becomes manipulation."

The claim is made that the operation is liable to be incomplete in the case of pus-sacs. No doubt this is true of the past, and perhaps at the present with some operators, but the youth of the operation accounts for this. The same objections formerly held good with abdominal section in such cases, as is shown by the number of inoperable cases that used to be reported.

Another objection is that viscera are more liable to be injured. This relates chiefly to the rectum, and is no doubt true, but in spite of it the cases do as well ultimately as similar ones done by abdominal section. Such cases when treated by abdominal section require drainage, and prolonged drainage, as a rule. This predisposes to hernia, so that against a temporary vagino-intestinal fistula in vaginal section one must put hernia with abdominal section.

Herniæ are not common after vaginal section, for if they were we would have heard more of them, in view of the long time vaginal hysterectomy for cancer has been a recognized and oft-performed operation. The claim that sepsis is more common is not borne out by the experience of operators. It is true that the average temperature after vaginal section is higher for the first two or three days than after abdominal section, but this applies only to cases in which the forceps instead of ligatures are used.

The same comment applies to the objection urged on the score of the offensive vaginal discharge. Here again the claim rests against the forceps rather than the ligature. But, after all, the objection is one readily controlled by proper vaginal douching, and is relatively an unimportant objection, when the advantages of vaginal section are considered.

Advantages. These briefly stated are: As much safety as abdominal section, and this, too, at its in-

ception, leading one to believe that with the same relative time and attention given to it that abdominal section has secured, it will be safer. The recovery is more rapid and the after-condition is better, because herniæ and omental and intestinal adhesions are less common.

at time of operation. The pudenda should be shaved; the vagina and cervix should then be cleansed, green soap and water being thoroughly applied with a brush. This measure must never be omitted, but if one case calls for the brush more than another it is the virgin vagina, the vagina with rugæ. Of course,

Fig. 2. Vaginal hysterectomy. Cautery knife in action.

Finally, we beg leave to say that, from all that has been said and done in this subject by the various operators, we might as well admit that a revolution is taking place in our methods of dealing with the uterus and appendages, and it is safe to say that most of the operations done now above the pelvis for conditions specified in this article will soon be done from below. It is merely a question of learning how to do it.

Operation. The diet should be light the day before, food being taken as late as six hours prior to operation. Twenty-four hours before the operation a brisk cathartic should be given. Six hours before operation the lower bowel must be thoroughly washed out by a copious enema of castile soap and warm water. The bladder should be carefully emptied

the upper surface of the external genitals, the vulva, the anal regions, and the buttocks must be subjected to the same process of cleansing, the brush being used sparingly on the delicate structures of the clitoris and vestibule. The entire surface, internal and external, must now be washed off with 1 : 1000 bichloride of mercury solution, and this in turn washed away with warm sterilized water.

When all this has been carefully executed, the patient is ready for any one of the several operations done by the vagina.

If the uterus is to be retained, and is to be curetted and packed, this step is now carried out. The débris of the curettage is then removed by washings of 1 : 2000 bichloride of mercury, and the patient is ready for the next step. Let us suppose this to be

an operation upon the appendages—some plastic or conservative procedure. In that event the operation is anterior colpotomy.

The body of the cervix is caught with a volsella just below the anterior utero-vaginal junction. Strong traction is then made (Figs. 1 and 2), while with the cautery knife a transverse incision is carried through the vaginal wall from one side to the other about coincident with the above junction. If the uterus is small, this incision need go no further than the sides of the cervix, and by this we mean the line of junction of the anterior and posterior halves of the cervix; but if it is large, it should be extended thence downward and outward half an inch or more, onto and through the latero-posterior vaginal wall. The bladder is next separated from the uterus, using the index and middle finger for this purpose (Fig. 3),

If it be the enucleation of a sub-peritoneal fibroid on the anterior face of the uterus—that is, anterior to the broad ligaments—we proceed to this at once, holding the field of operation against the vaginal incision by pressure from above. If it be the removal, in whole or in part, of an ovary, a tube, or the enucleation of a fibroid at the fundus or on the posterior face of the uterus, posterior to the broad-ligaments, we antevert the uterus and bring the fundus and body through the vaginal incision into the canal (Fig. 4). This can be best done by bringing through first one of the cornua, after which the remainder of the organ is made to follow. Several instruments have been devised to further this step, which is the most difficult in the operation, but nothing is so good as the two fingers of the operator working through the incision, aided, if necessary,

FIG. 3.

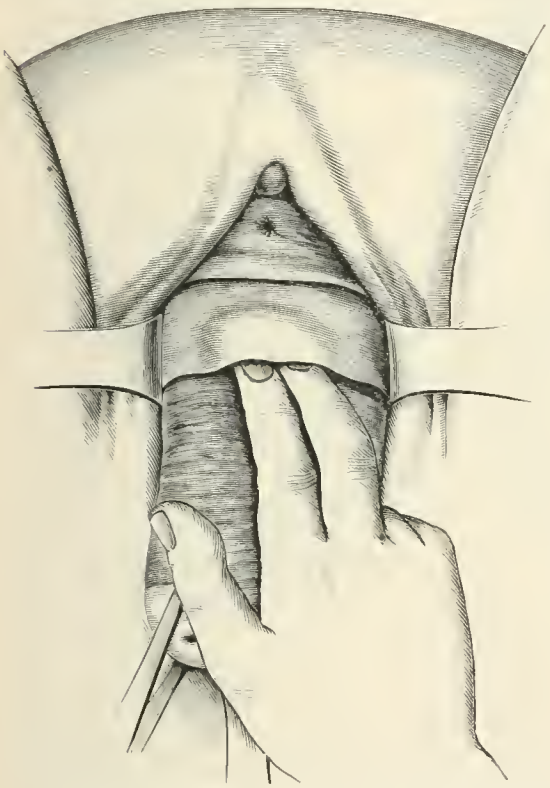

FIG. 4.

Fig. 4. Anterior colpotomy. Fundus uteri and left ovary drawn into vagina.

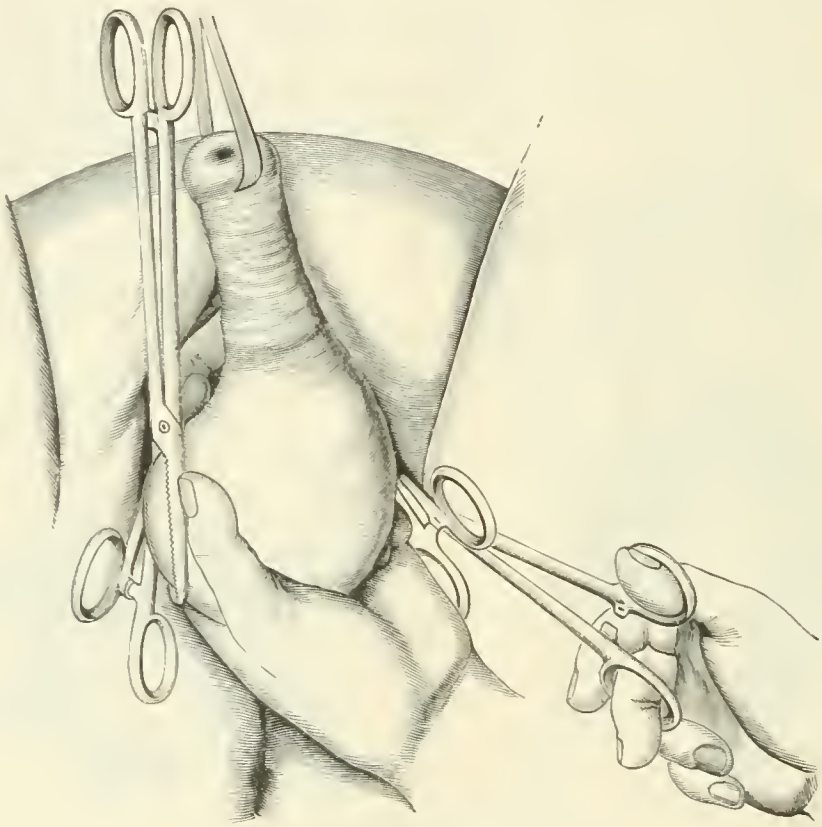
and the utero-vesical fossa is entered. Sweeping the fingers right and left, the bladder and ureters are pressed well aside. Still using the two fingers, the several viscera, including uterus, broad ligament and appendages, intestines and bladder are carefully palpated. Finding the conditions favorable to plastic or conservative operations upon the uterus or appendages, we proceed according to the problem presented.

by those of an assistant, placed in the rectum for the purpose of keeping the uterus forward. After the organ is drawn well into the vagina we act in accordance with the problem before us. Fibroids are enucleated upon the same plan as prevails under other circumstances—that is, the capsule is cut through and the growth seized with a volsella, and is worked out of its bed with the aid of the fingers and the scissors. Deep sutures of catgut or fine silk

are then passed, for the double purpose of closing the opening left and checking hemorrhage. If the ovary is to be operated upon or removed, it is drawn through into the vagina (Fig. 4), being reduced in size where necessary by aspiration or incision. When in the vagina it is at the command of the operator, and can be removed in whole or part as need demands. These statements are applicable to the tubes, which should also be brought out into the vagina, being previously emptied of fluid contents by aspiration.

involved bruising of the vesico-vaginal connective tissue, the cut in the vaginal wall may also be closed. If the contrary has been the case, it is best to leave the cut open. It may be sometimes necessary to pass from anterior colpotomy to hysterectomy, as where, for instance, we discover that both tubes are purulent and that the ovaries are similarly involved. This can be easily done by carrying the incision around the entire utero-vaginal junction, and then proceeding to the removal of the uterus, as we shall

Fig 5.



Vaginal hysterectomy. Forceps applied to lower segment of the right broad ligament and ovarian artery.

The ligation and removal of an ovary (which should be done independently) are, in general, simpler than the same operation upon the tube, because of the more extended blood-supply of the latter. In removing a tube tie as much of the mesosalpinx as you can, this generally is all of it; then ligate the uterine end of the distribution of the ovarian artery by including every structure at the cornu, except the tube; hug this closely with your ligature. Next enucleate the tube, and tie such bleeding points as appear. Having completed the operation, the uterus is returned to the abdominal cavity, and the divided peritoneum of the utero-vesical fold is reunited with catgut suture. If the operation has not

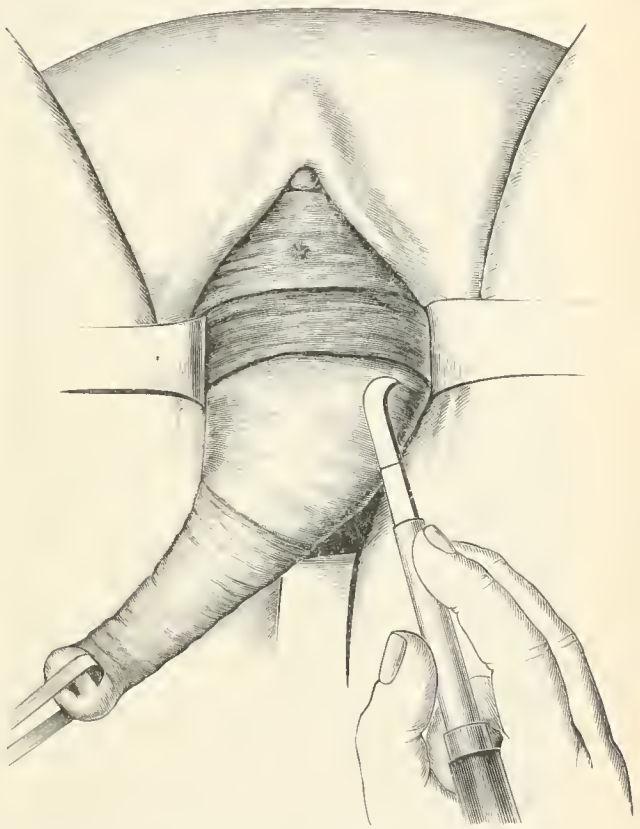
next describe under vaginal hysterectomy, with evacuation and removal of diseased appendages, such as pus-tubes, ovarian tumors, etc.

Posterior colpotomy. This section is resorted to for purposes of simple drainage, as in acute affections involving the cul-de-sac. It is also a part of the operation which looks only to the evacuation of pus-sacs, the removal of small ovarian tumors, the severing of adhesions, and exploration of the pelvis. It consists of a vertical section of the posterior vaginal wall, extending from the utero-vaginal junction to the bottom of the cul-de-sac. It can be made with knife or scissors, as there is small risk of hemorrhage, and, as a rule, can be closed when the work is done,

unless pus or some such infecting substance as the contents of a dermoid has been encountered.

Vaginal hysterectomy, with evacuation and removal of diseased appendages, such as pus-tubes, ovarian tumors, etc. It is assumed that the patient has had the usual preparation, that the bladder and rectum have been emptied. A soft rectal bougie should now be carried into the rectum and passed as far as it can be gotten to remain. The vulva and the vagina having been cleansed, as already described, and the cavity of the uterus, and especially the cervical portion of it, having been curetted and washed out with a solution, 1 : 1000, of bichloride of mercury, the removal of the uterus should be the next step. The cervix is grasped back and front with a blunt volsella and drawn forcibly down as near the vulva as possible. The vagina at the utero-vaginal junction is then cut through entirely around the uterus (Fig. 1). This accomplished, the enucleation of the cervical portion is next in order (Fig. 2), to be followed by measures designed to control hemorrhage. If it be by ligature, this is passed first on one side, then upon the other, so as to secure the uterine artery, which can be easily palpated. If, on the contrary, the clamps be preferred, one is placed on each side, so as to secure the entire lower half of the attachment of the broad ligament to the uterus, which will include the artery. These clamps are made to hug the uterus as closely as possible, and are guided into position by the thumb and index, or index and middle, fingers, thrust one in front and the other behind the broad ligament, at the uterine attachment. The vessels of the lower segment of the uterus being secured by clamp or ligature, the organ is cut free and the enucleation is carried on with the index and middle fingers (Fig. 3) until the bladder is separated and the utero-vesical space in front and the cul-de-sac behind have been opened into; the vessels at the sides are not molested, the vaginal wall being merely pressed back to give easy access to them when ligatures or clamps are to be applied. If the case is simple, that is, if there is no extensive matting together of the visceræ, as in bad cases of suppurative disease, the peritoneum upon the base of the bladder and in the cul-de-sac should be attached with a single stitch (catgut) to the corresponding vaginal wall. The way is then clear for the application of the clamp or ligature, as one may elect, to about its middle, still applying steady traction; the upper attachment of the uterus is next brought down; this is clamped (Fig. 5) or ligated, after the manner already described, and then the entire uterus is cut out. The succeeding steps depend upon the condition presented. If it be a simple pyo- or hydrosalpinx, these, along with the degenerated ovaries, are enucleated by the fingers, aided by long forceps, and are then clamped or ligated at the attachment to the broad ligament and cut away. If it be an ovarian tumor, this is drawn down to the cut in the vaginal roof, is there tapped, and after the contents have been removed the sac is withdrawn much after the manner which prevails with abdominal section.

FIG. 6.



Vaginal hysterectomy. Enucleation of uterus with cautery knife without clamp or ligature.

The serious difficulties arise in connection with the conditions of pelvic abscess. We may not be able to remove the uterus as cleanly as has been described, but may be forced to take it out by morcellation. Cut it out segment by segment, clamping the bleeding vessels as they appear. The posterior lower half is first removed, then the anterior. In this procedure we may open promptly into a pus-sac in the cul-de-sac. After cleansing this out, we proceed to the upper half of the uterus. This should be cut open antero-posteriorly. After removing the two segments, we use the cut ends of the cornua as guides to the pus sacs, tubes, and ovaries of either side. Feeling one's way carefully, making traction upon the sacs, which by this time can be differentiated, first one side then the other is drawn down, enucleated, and withdrawn. It may be that this process of enucleation will have to be

done in the depths of the pelvis; if so, one cannot use too much caution, for it is in such cases that visceral injuries are most liable to occur. Patience and intelligent perseverance will enable one to surmount the difficulties, however, so it is rare that one will be forced to call to his aid abdominal section. This, however, should be done if the intestines high up in the pelvis have been injured. Having opened above the pubis, the patient should be thrown into the Trendelenburg posture and the injured intestine quickly found and repaired. If any sacs, or parts of sacs, remain they should be taken out; the pelvis must then be washed out with sterilized water and a loose gauze drain placed in the bottom of the pelvis, extending thence through the vagina.

After vaginal hysterectomy of any kind it is wise to leave the vaginal cut open, draining through it by means of a good strip of gauze, which extends from the depths of the cul-de-sac to a proper dressing over the vulva. This precaution may be optional in clean cases, but it is an absolute necessity in all pus-cases.

If ligatures have been used, they are left long, are tied together, and placed in the vagina. If clamps are employed, they are looked over carefully to see that each is secure, doubtful ones being further guarded by tying the handles firmly together. The handles of the clamps are then encircled with a thick layer of absorbent cotton, which is also in contact with the vaginal drain, whose function it furthers. A soft-rubber retention-catheter is finally placed in the bladder, and the operation may be said to be complete. The catheter is self-retaining, by reason of a bulb or collar at the vesical end of the instrument, but to realize its object it must be plugged or knotted at its free end. By removing this plug or knot at intervals of two or three hours the bladder is properly emptied and the dressings are kept clean. This upper cotton dressing and the catheter are the same for all cases of vaginal section.

This article would not be complete were we to omit mention of the method of removing fibroids by morcellation.

The preliminaries up to and including separating the vagina from the cervix are identical with the process already described. The departure begins after the cervix has been enucleated, and the lower vessels ligated or clamped. This consists in cutting away, piece by piece, first the cervix, then the body of the uterus, dragging each piece forcibly downward with blunt-toothed volsella; bleeding points are caught as they appear and ligated or left in the keeping of the clamps, as convenience dictates. Working after this fashion, with knife and scissors, protecting the vaginal walls with retractors, the tumor is dragged piece by piece into the vagina, and then cut off. In this way the operation is really performed within the vagina, sparing the cavity above it. As already intimated, the dressing and later treatment of the case coincide with those adopted in other vaginal sections.

A word must now be said about enucleation without clamps or ligature. It can be done, but it has its limitations, and should be performed with the cautery. We confess that a ligated or clamped vessel makes us less anxious, and as there is no valid objection which is at all weighty, we prefer to use one or the other.

The best cases for this operation are women past the menopause or who have already been rid of their appendages—the uterine vessels being with all such persons more or less atrophied.

It is done as follows (Fig. 6): After the usual preparation, seize the uterus at the cervix and burn through the vagina at the utero-vaginal junction. Now keep up forcible and continuous traction upon the cervix, at the same time burning through the attachments to the uterus as they descend. This burning must be made within the true uterine tissue rather, the cautery being driven firmly into it. It is best after each segment has been burned through to relax the traction, to see if the vessels just severed bleed; if they do, sear them at once, and continue it until they are closed. Proceeding in this manner the uterus is quickly peeled from its envelope, and the cornua are brought into view. These are burned through and their stumps seared. In the removal of the tube and ovary it is wiser to use ligatures or clamps. This having been done, the operation is complete. The after-dressing and treatment are the same.

Speaking now of vaginal hysterectomy in general, clamps should be removed in from forty-eight to seventy-two hours, after which the patient should receive a night and morning douche of warm boric acid or permanganate of potash solution, for purposes of cleanliness and comfort. Ten days cover the usual limit of convalescence in bed, the patient being permitted, under ordinary circumstances, to take the sitting position in bed at the end of a week. The catheter should be removed when the clamps are taken off. Ligatures should be cut out at the end of two or three weeks. The bowels are treated much as in abdominal section, but there is one comfort the patients with vaginal section can enjoy, that is, morphine for the relief of pain. This drug does not appear to have as troublesome consequences after this form of operation as after abdominal section. With this, Mr. President, I must close.

Recapitulation of conditions favorable on the one hand to vaginal section, on the other to abdominal section in diseases of the female pelvic organs:

Vaginal Section.	*Abdominal Section.*
1. A shallow and wide pelvis in a thin woman.	1. A narrow and deep pelvis, especially if deformed.
2. Explorations of the pelvis.	2. Explorations above the true pelvis.
3. Visceral adhesions in true pelvis.	3. Visceral adhesions in false pelvis or above.
4. Displaced and adherent uterus.	4. Large ovarian cysts, especially multilocular, with colloid contents.
5. Smaller ovarian cysts, especially the intraligamentous and parovarian.	5. Large fibroids, especially the firm and hard.
6. Smaller fibroids, especially the soft.	6. Extra-uterine pregnancy at time of rupture and at term.
7. Extra-uterine pregnancy, up to seventh month, and after death of fœtus.	7. Extra uterine pregnancy, with tumor wholly above brim of pelvis, and not in relation with uterus.
8. Pelvic hæmatocele.	8. Pelvic abscess pointing upward.
9. Puerperal hysterectomy.	9. Conservative operations under conditions unfavorable to vaginal section, such as a narrow and deep, or a deformed pelvis, that is contracted.
10. Acute inflammation of appendages, with peritonitis involving cul-de-sac.	
11. Inflammatory destructive diseases of the appendages, including tubercular disease.	
12. Pelvic abscess pointing downward.	
13 Conservative operations on appendages that lie in true pelvis.	

THE THERAPEUSIS OF THE SAINTS.

By WALTER L. PYLE, A.M., M.D.,
OF WASHINGTON, D. C.;
FELLOW OF THE AMERICAN ACADEMY OF MEDICINE; FORMERLY RESIDENT PHYSICIAN IN THE EMERGENCY HOSPITAL, WASHINGTON, D. C.; MEMBER OF THE MEDICAL ASSOCIATION OF THE DISTRICT OF COLUMBIA, ETC.

THE modern instances of the belief in simple faith or superstitious worship in the cure of disease, as exemplified in the almost daily reports of marvellous recoveries attributed to the efforts of "faith-curists," "mind-healers," "layers-on-of-hands," and the like, furnish this century's analogue of the ancient custom of invoking the aid of the saints in the relief of the afflicted.

Superstition, Paul Lacroix has said, is the inevitable consequence of every religion or Deism, and to the simple, ignorant mind it naturally becomes more powerful than the religion itself, being more awe-inspiring and impressive. In the history of all nations and peoples the superstitious belief in the efficacy of deified personages in alleviating pathological lesions has prevailed.

In the ancient Pagan times the divinities were the precursors and parents of pathology—the old gods are dead, but the heavens and the maladies still retain their intimate relations. The patrons, once placed in Olympia, were transferred to Paradise. In the heaven of the old Pagans there were supposed to be lodged a long succession of gods and goddesses, whose province was to look over the diverse maladies of humanity. The material sheath of our soul, with its miseries external and internal, was supposed to be carefully guarded by this collection of deities.

The matrons contemporary with Augustus Cæsar well knew whom to address for the correct manipulations and treatments of childbirth. In the first instance they prayed to Pertunda to facilitate advantageous union or meeting of the sexes. Then followed appeals to Mena, on whom depended the regularity of menstruation. Materprema had a special mission in keeping the uterus in condition for the proper reception of the male seed.

Having carefully and successfully pursued their respective functions up to date, these deities were dismissed, and, conception happily ensuing, Fluonia was summoned to care for the growing germ in the womb, and keep out the evils of abortion and miscarriage.

Then grand Diana stepped in, and looked to the preservation of the life of the fœtus. Juno Postversa labored to put it in good position, and stepped aside for Lucina, who was famous for her ability as an obstetrician, and with her little helpers, the Nixii, who pushed hard for the contractions, effected a safe delivery.

The members of the Celestial aristocracy having successfully brought the child to light continued their monopoly in the person of Jupiter Diespiter, or possibly Cunina, to whose care the life of the child was entrusted. Throughout the period of lactation, with mystic passes over the breast, Rumilia produced a sufficient flow of milk.

Turning now to the more enlightened Christian woman of the latter period, we find her still happy in the protection of the plethoric heaven of sanctified personages, but to a less degree than her Pagan sisters. With the advent of Christianity, Saint Agatha replaced Rumilia in exercising an influence, for good or bad, as the case might be, over the female mammæ. Invocations to her were deemed the best means of relief from mammitis. The older Christain woman addressed her prayers to Notre-Dame-de-Montserrat, Saint Marguerite, and worshipped at Lourdes and at the statue of Saint Guignolet. The latter will soon be a thing of the past, if its original does not acquire a better degree of proficiency, as it is fast disappearing under the scratches of sterile husbands.

Happily, if parturition is seemingly neglected by the saints, the pathological disturbances of the human body are plentifully supplied with patrons and patronesses from this overworked society, each of whom has a designation, either curative or causative, in some disease. Saint Guy had under his

domination the neurosis, chorea, often called "danse de Saint Guy," or St. Vitus' dance. Formerly they danced before the chapel of this saint to be relieved; but since the discovery of the efficacy of arsenic Saint Guy is neglected, and the neurologist has usurped his domain. Saint Giles struggled with the hopeless task of carcinoma, besides lending adjunctory assistance to the others in the obstinate cases of epilepsy. Saint Gervasius gave many a sharp reminder to the unfortunate under his care, and has to-day a deadly rival in the lithiates and salicylates. His rheumatic clients are rapidly forsaking him, and, in fact, his memory is only perpetuated by an occasional charm or amulet among the lower classes. Saint Genou is fortunate in the possession of two helpers in the cure of gout, viz.: Saint Mor and Saint Gueslain. Coquillart bears witness to the efficacy of the former in his *Monologues des perrecques*, in which is seen "I come to Saint Mor des Forrez to be relieved of the gout." Homage is rendered to both these auxiliary saints in the old comedy, "Pasté et de la tarte," in which a character cries out,

"Que la goutte
De Sainct Mor et de Sainct Gueslain
Vous puyssiez tresbucher a plein."

In cases of toothache, each jumping pain was considered the individual handiwork of Saint Apolonia, and to her the victims of this distressing minor ill looked for relief. Our *confrères*, the dentists, have played sad havoc with this saintly lady, and, like Othello, "her occupation's gone."

By his good offices Saint Main saved the itching commoner from scratching. If we can correctly judge from a passage in Ambrose Paré (des Venins), this same individual brought succor to individuals afflicted with dermal manifestations of syphilis. Paré says: "An ointment of quicksilver cures what is called commonly the malady of Saint Main;" and, after a glance through the *Commentaires sur Dioscoride* of Antoine du Pinét, we are lead to believe that this saint looked after other cutaneous eruptions such as tetter, eczema, milk rash, etc.

Saint Reine was a valuable constituent of this sanctified system of therapeusis, curing thrush and scald-head. Having recovered from a severe and terrible fever, this Saint went to church to give thanks for his recovery. Jesus was duly thanked, but, turning to a picture portraying Saint Anthony with a white beard, he said: "Y no a vos, barba blanca, que tan mal su fuego me trato, y me quemo en mis calenturas." This warrior was not willing to thank Saint Anthony with his white beard for the fire that had almost consumed him during his fever.

Saint Avertin, Saint Romain, Saint Gildas, and Saint Mathelin divided among themselves the various forms of mental aberration. In the very early days Gheel seems to have been a kind of Lourdes, for, according to the *Cornhill Magazine*, a certain St. Dympna, who lies buried there, was supposed to have *les faibles d'esprit* under her special protection. It was the custom, therefore, throughout the Netherlands for persons who had insane relatives to take them to her tomb and there offer special prayers to her for their recovery. If tradition is to be relied upon, the saint was by no means loath to give proof of her beneficent power, and wonderful stories are told of the way in which she used to restore reason to those who had lost it. Still, even in those times miracles were not wrought every day. Some of the sufferers who went to Gheel had to wait for months—nay, years—before they were healed, while others were never healed at all. And while waiting they had to be taken care of. At first the innocents, as St. Dympna's *protégés* were called, were all lodged in little huts or caves around the church, but as the fame of Gheel spread abroad they increased in number, and it became necessary to make other arrangements. They were then boarded out with the peasants living in the village, and there were so many of them that at length every family had its innocent. If a child was constantly crying and fretful, says Panckoucke, in his *Dictionnaire des Proverbes*, he was committed to the care of Saint Avertin. In his *Harangue de Midas*, Bruscambille writes: "There is no receipt compounded by any doctor or apothecary, no matter how wise, which is potent in the malady of Saint Avertin."

Saint Eutrope was supposed to cure hydrops, as we can see in the nouvelle cxxix of Bonaventure des Periers; but the invocations to this patron were in vain in the celebrated case of Louis XI. If M. Chéreau is well informed, Saint Eutrope (eau trop) is but one of that series of saints whose province originated solely from a quibble or witticism on their name. Eugène Noël advanced this theory, and gives a few examples. Saint Genou, who was the solace of those afflicted with rheumatic or gouty joints, was probably one of the number; Saint Mammard (mammelle) ripened the abscesses of the breast; Saint Marcou (mal au cou) was supposed to have the power of effacing scrofulous marks and curing the King's evil; and Saint Fiacre carried solace to those unfortunate enough to suffer from affections about the anus—particularly vegetations—from the resemblance of Fiacre to "fic."

F. Brémond says the hypothesis of Noël becomes an absolute certainty in the case of the patron of the inhabitants of Lourcine and the Hospital du Midi, and quotes the interpretation of the name of this saint as given by his master Jacob. "The recoveries are divided between the saints, who take

the monopoly of cure to themselves, and sometimes a saint has been invented expressly for the malady, as, for example, when the venereal malady first made its appearance there was soon found, where no one knows, a Saint Foutin to take the pox-stricken sufferers under his auspices."

From the North to the South, the saint most respected in sacred therapeutics is Saint Hubert. The number of individuals that he is reported to have cured of the "rage," or hydrophobia, is incalculable. He was given, it is true, the assistance of Saint Mathurin, but what help is he to the great patron of the chase, whose name is as familiar to the smooth chin as to the white beard, and we dispense with details, for this great patron had a glory which admits of no addition.

In the middle ages Saint Lazare was the busiest of all. In our times he is virtually in a lethargy of idleness. It is true that we continue to call some of the sanitary stations "Lazaret," but these are nearly always empty, and when they contain a patient his malady is far different from those of olden times. Saint Lazare was the guardian of the leprous, more commonly called in France "ladres" or "mesels." In the 18th century, in France alone, there were more than two thousand hospitals for lepers. To-day, thanks to science, the universal vanquisher of cant, hypocrisy, and superstition, a case of leprosy is cause for excitement and discussion in all the journals and among those versed in this pathological rarity.

Saint Sebastian was invoked for the "peste venenosque," and had for his assistant Saint Roch. In *les Aventures du Baron de Foeneste*, d'Aubigné shows a Gascon who had fallen into the charnel-house of the plague-stricken, and employs his priest to say a mass to Saint Roch. Like this Gascon, the pious inhabitants of a certain village in Provence, even to the 19th century, cry once a year "misèricorde" in the chapel of Saint Sebastian. In the south of France Saint Hermantaire is still supposed to look after children who are timorous, nervous, or who are subject to convulsions, and Saint Victor calms their fever. If one consults him, devout inhabitants of Marseilles will tell you that, after the Virgin Mary, no one possesses the power of more miracles than Saint Victor.

Saint Gerbold was much occupied with dysentery, while Saint Regnauld was not indifferent to those suffering with affections of the bladder. In all cases of colicky pains, whether from excesses in eating or otherwise, supplications were addressed to Saint Erasmus. To the bibulous was given a patron in the person of good Saint Martin. Needless to say, few candles were burned for him, as curing the evil in this instance was worse misfortune than its continued existence.

If we consult Henry Estienne's *Apologie pour Herodoté*, in the preface of his edition of that great historian's work, we find that the curious duty of Saint Bernardin was to keep a guardian eye over the "suffocations of the matrix." If one should be asphyxiated, for relief he would invoke the aid of Saint Eloi.

The last alphabetically of this long list of pathological patrons was Saint Zachary, who cared for the dumb.

Félix Brémond, who was called to account by a friend for his campaign against superstition, and was accused of citing the customs of olden times with the present day in his arguments, denied the anachronism, and, among others, quoted from page 198 of *Pèlerinage de Saint Hubert*, by Abbé Bertrand, printed in Paris, 1869, the following: "In order to prevent the 'rage' they carry devoutedly on them objects blessed or which have touched the miraculous stole of Saint Hubert, such as crosses, rings, chaplets, etc." M. Brémond also produced modern books in which were a prayer to Saint Christopher to keep off sudden death; an oraison to Saint Vite for defence against the rage of ferocious animals; an invocation to Saint Blaise for the cure of sore throat, and a pious invocation to Saint Magnus for protection against venomous insects. M. Brémond, in addition, promised his friend a copy of Paul Parfait's *l'Arsenal de la dévotion*, in which he could revel in superstition to his heart's content. M. Brémond, on reading that the Queen of Spain was expecting her confinement, and had been provided with a bone of Saint John the Baptist, the comb of the Virgin Mary, containing three of her hairs; a chemiset of N. S. Jesus Christ, together with a reserve relic in case the fœtus would exhibit signs of recalcitrant royalty, the body of blessed Diégo de Alcala, suggested in his piquant, skeptical French manner, as a grand completion to this arsenal of saintly obstetrical aids, the following:

1. A wax taper from Notre-Dame-de-Montserrat, which the reverend Pierre de Bourdeilles, Lord of Brantôme, declares, in his fourth chapter of *Des dames galantes*, a strong aid to the Spanish ladies in childbirth.

2. The reliques of Saint Marguerite, which served Marie de Médicis so well, as told in the works of the celebrated midwife, Louise Bourgeois. But despite the assistance of the relics and the incessant prayers at Saint-Germain-des-Pres., she lay in agony 22 hours.

3. A piece of the robe of Saint Ignace, which R. P. Terwecoren says is equally efficacious to the mother fearing pregnancy, and the female who trembles lest the soft name of mother will never greet her ear.

4. An agnus ot white wax coming from the Chapelle Sixtine, which the Canon Barbier de

Montault remarks protects both mother and child during pregnancy and deliverance, and shortens and ameliorates the throes of labor.

5. A cordon of blue wool from Saint Joseph to expedite matters; for, says R. P. Huguet, "what is impossible for the doctors is easy for Saint Joseph."

6. The oraison of Sainte-Croix discovered in 1550, and reprinted in 1880, in Paris, in which are these words: "When a female finds herself in pregnancy, she is expected to read or repeat this prayer, or to carry it on her, and she will be expeditiously delivered; she will remain a tender mother, and when the infant is born, if the prayer is placed on its right side, it will be preserved from a great number of accidents." After generously offering these suggestions to the royal Christine, M. Brémond adds:

7. *A pair of forceps.* It happens sometimes that this instrument is not unuseful in accouchements, even of royalty. In the case of another Spanish woman of the royal blood, Eugénie de Montijo, in spite of a strong armament of saints' bones collected by herself and her august spouse, the "fers de l'accoucher" sensibly flattened the ears of the youthful scion, who was called by Cassagnac "Napoleon IV.," and who eventually offered up his life to the British Government in the war with idolaters in Africa.

To complete the list of the virtues and powers ascribed to the saints would take this short sketch too far. At first glance, many of these facts seem exaggerated and almost incredible; but when we have before us in our own day the much-vaunted powers of the waters of Lourdes, with their enormous patronage, drawn from the high as well as the low classes, and from every section of the world; the almost daily pilgrimages to other famous wells and shrines; the custom, still extant, of the exposition of saintly relics for therapeutic purposes; the frequent account of faith-cures in this country as well as in the old, we can readily believe that the world is by no means lifted from its superstitious ignorance by the rapid advances of pathology, and, strange to say, the very countries that have done most to advance science are the most tenacious in their old medieval fears and faiths.

CLINICAL MEMORANDA.

EXTENSIVE LACERATION OF THE ABDOMINAL WALL BY A BULL'S HORN; EXTRUSION OF THE INTESTINES; OPERATION; RECOVERY.

By JOHN A. WYETH, M.D.,
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; VISITING SURGEON, MT. SINAI HOSPITAL.

J. D., male, aged fifty years, a strong, healthy farmer, weighing about 180 pounds, was gored by a bull at 9 A.M., July 21, 1893. As the animal rushed at and lifted him, one horn penetrated the left trouser-leg six inches below the groin, scraped the skin along the thigh upward until it struck the protruding abdomen one inch above Poupart's ligament and just outside the internal abdominal ring, where it penetrated the peritoneal cavity and ripped the abdominal wall obliquely for five inches from this point in the direction of the free end of the twelfth rib of the left side. The laceration in the skin was less extensive than in the muscular layers, although the integument was dissected or torn loose from its subcutaneous attachment for four or five inches in all directions from the upper margin of the wound. The other horn struck the patient just below the left axilla, tearing an ugly gash in the axillary space, dividing some of the vessels of the pectoral region, but, fortunately, not wounding the larger vein, artery, or nerves. In descending, the patient fell on the back of the animal, rolled to the ground, and scrambled to his feet. As he stood up he felt his intestines rush out into his clothes, and then fell unconscious. He was carried to the house, put to bed, and Drs. Card and Owen, of Mahopac, summoned.

I saw this patient at 6 P.M., nine hours after the accident. As it was getting late, every haste was made for operation. Chloroform was used. A large mass of small intestine, congested but not strangulated, dotted here and there with hair, shreds of clothing, and several bruised and dark spots, varying in diameter from one-fourth to one-half inch, protruded through the opening in the skin. A finger carried into this opening recognized a second and equally large mass of intestine lodged in a pocket between the muscles and the loosened integument. The opening through the skin was freely enlarged in order to expose the entire mass, which was now irrigated with hot boric acid solution (gr. vij to ℥j of water, boiled and allowed to cool to about 110° F.). A finger carried through the lower angle of the laceration in the muscular wall satisfied me that there was no intraperitoneal rupture with escape of intestinal contents. A mass of omentum, covered with clot and hairs, was tied off with catgut sutures, and the stump was later returned to the peritoneal cavity. Commencing at this angle of the wound a careful toilet of the intestine was made, after the entire mass had been irrigated as described above. Hot towels enveloped the coils above. Section after section of six inches each of gut was isolated and washed with soft, small sponges, wet in hot boric acid solution and squeezed nearly dry. The mesentery, from the deepest portion of the wound, was exposed and cleansed on both surfaces up to the intestine, and then this was gone over and returned to the peritoneal cavity. This process was repeated as rapidly as was consistent with thorough cleanliness until the entire length, estimated at fifteen feet, was reduced. The ragged edges of the torn muscles were trimmed where long shreds were hanging, a twist of iodoform-gauze was carried into the peritoneal cavity and out at the lower angle of the wound for safety drainage, in case of infection, and the wound closed by a single row of silk sutures passing through skin, muscles, fascia, and peritoneum, with tight approximation of the edges, except at the drain, where a single suture was only fairly tightened. The time consumed was one hour and forty minutes.

On the fourth day the temperature of the patient, which up to this time had not been over 100° F., reached 102° F., and there was considerable pain in the wound

at its lower portion. The twist of gauze was removed, and about half an ounce of odorless pus escaped. A smaller twist was reinserted, and this was removed daily for three or four days, when the discharge ceased. Nothing of interest occurred after this, and the patient recovered.

At this time, more than two years after the operation, the man is well. There is a small ventral hernia at the lower angle where the gauze drain emerged, the scar protrudes perceptibly, and, on coughing, a localized impulse is evident.

In analyzing this case some points of interest are suggested.

What should be the immediate management of cases where the intestines protrude?

(*a*) The arrest of hemorrhage is, of course, an immediate and vital necessity, but, fortunately, it is seldom a dangerous complication. The extrusion of the intestine takes place rapidly, and usually is so extensive that the large mass of omentum, mesentery, and gut arrests ordinary bleeding by self-compression at the opening in the abdominal wall. When bleeding occurs it should be controlled by catgut ligature or warm towel or gauze compresses.

(*b*) It is always advisable to restore the viscera to the peritoneal cavity as soon as possible. If, for any reason, this is not undertaken, the protruding organs should be kept warm and moist by being enveloped with towels or napkins, wet and kept moist with hot bichloride solution 1 : 10,000, or boiled water cooled down to 110°–120° F. The solution should not be carelessly employed, for, though absorption is limited from the exposed surfaces, a considerable quantity may leak into the general cavity of the peritoneum, with harmful result. Complete anæsthesia is essential when reduction is undertaken. For the final toilet of the soiled viscera I prefer the boric acid solution, but have also employed the 1 : 10,000 bichloride solution with good effect.

(*c*) The method of suturing wounds through the abdominal wall is of great importance. I am convinced that fewer ventral herniæ occur after the suture heretofore described than by any other method. Moreover, it occupies much less time than when a separate peritoneal suture and one or two muscular and cutaneous rows of suture are inserted.

(*d*) In all instances where a considerable mass of intestine has been exposed and is soiled, no matter how careful the toilet, it is advisable to insert a twist of iodoform-gauze for safety drainage. This precaution saved the subject of this report. It is usually removed on the third or fourth day, the sutures on the eighth or ninth day.

(*e*) In order to prevent adhesions between the exposed and inflamed coils of intestine and to forestall intestinal paresis, which occurs with peritonitis, this patient was given saline laxatives twice a day, commencing on the morning after the operation, and securing two or three movements a day for four or five days. Epsom salts and Hunyadi water were employed. Calomel triturates, gr. j–ij, at night are safe and effective. The minimum of morphine should be administered, and none at all if it can be dispensed with.

(*f*) After an extensive wound or incision in the abdominal wall a patient should not be permitted to bring any considerable strain upon the part involved until thorough union has been secured. I usually require six weeks in bed or about the room, and the recumbent posture for at least four weeks.

(*g*) An accident occurred during the operation which came near proving fatal. But for a precaution which should invariably be practised, and prompt action by all engaged, the patient would have perished on the table. On account of pain and shock, the attending physician had administered morphine in considerable quantity. This so dulled the respiratory sense that during the operation, and just as the last loop of intestine had been restored, although a very small quantity of chloroform had been used, the patient ceased to breathe, became almost instantly cyanotic, with jaws tightly clinched. With special forceps, pointed so as to take advantage of the slightest space or unevenness between the upper and lower rows of teeth, the under jaw was pried open, the tongue seized and drawn out, and artificial respiration by Sylvester's method performed. After several minutes of anxiety (at least five minutes, by common estimate of the five physicians present) the natural respiratory effort returned, and the operation was finished without further narcosis. I have in a number of instances seen death from arrest of respiration prevented by this precaution, without which, it seems to me, an anæsthetic should never be given. A wooden screw or wedge for separating the jaws, and a strong fixation gag, and forceps for holding them fast, a fixation forceps for the tongue, and sponges on holders are the essentials.

URETHRAL HEMORRHAGE; HÆMOPHILIA.

BY CAPTAIN A. E. BRADLEY, M.D.,
CAPTAIN AND ASSISTANT SURGEON, U. S. ARMY, FORT YELLOWSTONE, WYOMING.

MR. L., after an alarming hemorrhage during the night, asked me to see him the following morning; the history obtained was this:

Occupation, merchant; aged thirty-three years; unmarried; parents and other members of family all in good health. About a year ago was treated for some time in a Chicago hospital for some obscure bladder trouble, probably cystitis. Since that time he has used occasional boric acid irrigations, and passed a sound monthly. Because of the cystitis he has been carefully observing his urine for sediment.

Two days prior to his present trouble he noticed a marked deposit in the bottle, which he described so as to lead me first to believe was pus, but later he said the urine was perfectly clear when voided and the sediment only appeared after standing some hours. It being a cold night, it may have been granular or amorphous urates; of this I cannot be certain. Microscopic examination showed no pus in the specimens afterward obtained. For some days he had had some vague discomfort referred to the right abdomen, but no pain. His habits are temperate, and he has not had sexual intercourse since July of the present year. His sexual desire, however, has been strong, and he has been troubled with frequent annoying erections both night and day. On the day preceding my visit he had been standing nearly all day bending over a low table working at photography; he remembers his erections were troublesome, but is not certain that he injured himself in any way.

About seven in the evening, and about one hour after passing normal urine, without any warning, his attention was called to a warm trickling down his thigh.

Investigation showed blood spurting from his penis in alarming quantities. It could be controlled only by grasping the organ tightly in the hand, release of the constriction being at once followed by the hemorrhage. A large bath-towel was saturated and the carpet showed two spots covered with clotted blood, not smaller than dinner plates. He believes he lost more than a pint of blood, and I think this is a small estimate.

He was much exhausted, and went to bed, though he slept but little, having occasional erections which renewed the hemorrhage. In the early morning he passed clear urine, which scalded one portion of his urethra and was followed by slight bleeding. He "milked" a clot from his urethra, which brought on hemorrhage again.

At noon he passed normal urine in my presence with no scalding, and but a slight trace of blood followed his milking process. He rapidly recovered his usual health.

I regret that I was unable to make an endoscopic examination. There was no infiltration into the tissues of the penis, and no pain except at one point near the scrotal junction, where there was slight tenderness, probably the source of the trouble. His abdominal uneasiness and the other symptoms first led me to think of renal trouble, which may indeed exist, but the hemorrhage was undoubtedly urethral.

Since childhood he has noticed a tendency to bleed profusely after slight injuries; nose bleed has many times given him much alarm; the hemorrhage from slight cuts, pin-pricks, scratches, etc., is controlled with difficulty, and a few years ago, while absent-mindedly biting his lips, he caused a slight abrasion from which blood spurted in alarming quantity. No other members of his family are bleeders, so far as known. While urethral hemorrhage may not be rare, I am unable to find in the works at hand any reference to bleeding similar to that which occurred in this patient.

CLINICAL LECTURE.

THE MEDICO-LEGAL ASPECT OF APHASIA.

By DR. C. K. MILLS.

A Clinical Lecture delivered at the Philadelphia Hospital.

Reported by M. V. Ball.

Aphasia has an important place in legal medicine not only from the fact that it is often combined with insanity, but because questions often arise as to the responsibility of the afflicted person or his testamentary capacity. In every case we must find out how far the patient is able to speak, how far he can make himself understood by speech, and how far he can explain himself by means of pantomime.

By pantomime we mean the use of signs for definite purposes, and it may be present with speech, and on the other hand it may be lacking, while speech is preserved. In bringing these patients before you, illustrating as they do various kinds of aphasia, I will dwell mainly on the medico-legal aspect of the subject.

In Case I. we have an old hemiplegic woman, who answers every question with a single recurring utterance, namely, "*la-la*;" she is paralyzed on the right side, and has been in the hospital many years; she understands everything that is spoken to her; she puts out her tongue when told. She plainly evinces her disgust by pantomime, when asked if she wants medicine, and yet the full extent of her vocabulary is "la-la."

Case II. is a man who replies to all questions with the two words, "*any one*." Here we see that the man likewise understands all that is spoken to him, but has only these two words to make his wants known.

Case III. says "*no*" to all questions, even when he means yes. Occasionally he utters an oath, but this utterance is involuntary and he is not responsible for it.

Case IV. is a man who cannot talk at all; when questioned he shakes his head. He understands what is said, but is unable to utter a syllable, although able to make his wants known in writing. There is no paralysis present, but as his trouble came on suddenly, and as the result of an accident, there was probably a hemorrhage.

Case V. is a woman, who, when asked her name, answered promptly, "B. Doyle;" when asked whether it was Bridget, she made some incoherent remark; when shown a penknife and told to name it, she replied that "she knew what it was, but could not tell the name of it;" when shown a key, she said it was for hiding things; a watch was called "money;" she said "she was going to say hammer, but she knew that is not right." After some effort she exclaims, "gold," and when asked if it is not a watch, she says, "yes, a hatchet." She is able to name correctly her hand and foot. This woman, like the others, is able to understand everything that is told her and has an extensive vocabulary, but certain words she cannot speak. She has a form of verbal amnesia. She is neither word-blind nor mind-blind, she recognizes objects and their uses; she can even recall the names of such familiar things as her hands and feet, but many other concrete nouns she cannot name.

Case VI. is a young woman who has been paralyzed for one and a half years. After the attack she had slight trouble with speech; she is an example of left hemiplegia. As a rule, only right-sided hemiplegia is accompanied by persistent aphasia, but when the person is left-handed, aphasia may be present in left hemiplegics.

Case VII. is a man who, when asked a question, responds, but in a very imperfect manner. He is neither demented nor word-deaf; he is able to make known his wants, but there is a paralytic condition of the muscles of articulation. The man has the power to propositionize, that is, to construct sentences properly and speak them.

Case VIII., an old man who is unable to stand without support, a complete hemiplegic, when asked his age, showed with his fingers that he was forty, but he looks at least sixty. He can only make a moaning sound, and, although understanding what is told him, is deficient in pantomime and resembles a demented person in his appearance.

Case IX. is a woman with verbal incoherency; she will start out well and then will come a word or phrase which has no connection with what has gone before it. Her language is a form of jargon. The patient is able to understand all that is spoken to her, and has a large vocabulary, but the speech is broken up by putting in words that do not fit; her reading is much like her

speech. Some patients read rapidly and fluently what is a jargon to others, the person reading understanding all the time what he is reading, but may not be understood by his hearers.

Having shown you these patients we will now test them in a medico-legal way as to their responsibility, The cases in which aphasics become involved are more often civil than criminal.

Aphasia, like deafness, tends to make a person emotional, impatient, quick to anger, and so occasionally crimes of violence may be committed in moments of passion that are clearly attributable to the infirmity. Insanity itself may be present. The insane wards of a hospital contain some aphasics, and so the same questions that apply to the insane in any court case may arise in connection with this disease. In examining an aphasic the question to be answered is not, is an *aphasic* responsible, but is this or that *aphasic* responsible. Hughlings Jackson illustrates the matter well when he says that the question at issue is not whether a piece of string will reach across a floor, but if this or that piece will.

One of the questions that may arise in a civil case is the one in reference to testamentary capacity, Can the aphasic make a will? Can he be held responsible for a note or any other piece of writing to which he has affixed his signature or mark?

Some years ago I was called to see a man who had been stricken with an attack of apoplexy, and who was living with a woman not his wife; after the attack he married the woman, and then dying left his money to her. An attempt was made to set aside the will on the ground that the man, being an aphasic, was not responsible. I could testify that he was able to understand everything I said to him when I saw him, and the will was allowed to stand.

Starr gives the following list of questions useful in examining cases of aphasia:

1. Has the patient the power to recall the spoken or written names of objects seen, heard, tasted, or touched?
2. Has the patient the power to understand speech and musical sounds?
3. Has the patient the power to understand written or printed words?
4. If he speaks voluntarily, does he talk clearly, does he mispronounce, does he misplace, or talk jargon?
5. Has he power to repeat a word after hearing it?
6. Is he able to read aloud, and, if so, does he understand what he reads?
7. Has he the power to write voluntarily, and can he read what is written?
8. Has he the power to write at dictation?
9. Has he the power to copy?
10. Has he the power to recognize the use of objects seen, heard, felt, or tasted?

The following is a subdivision: Has the patient the power to communicate his thoughts by pantomime? The power to understand signs, as well as expressing them, may be lost in some cases.

Let us test Case III. You remember his vocabulary consists of one word, "no." I hold a pen before him, and ask him if he knows what it is; he has not the power to name the object. When told to put out his tongue he does so, therefore he understands what I tell him; but when I ask him his age, he continues to put out his tongue. This is probably mere confusion from the examination, though it should be noted, as it may have some bearing in the matter. I ask him if the word on this paper is New York; he shakes his head in a negative manner. Is it Philadelphia? He moves his head in assent, it being correct. So we see he has the power to understand printed words. Further testing shows that he also understands writing. He can talk voluntarily only to a very limited extent, and only in monosyllables, as "no" and "no, sir." He cannot repeat words or letters, but, strange to say, he can count up to sixteen without any effort. Sometimes he talks a little jargon. This man knows what he wants to say, and understands what is spoken to him, but he will say "no" when he means "yes," and he is easily confused. He will not write to-day, although he has written a word or two on another occasion. He can make his wants known only with great difficulty, and therefore might be understood as meaning one thing when he meant another. The man has a motor aphasia, probably due to a lesion in and around Broca's convolution, with destruction of tissue in the neighborhood. He has a motor aphasia, a motor agraphia, and a loss of pantomime almost equal to his loss of speech, becoming very much confused when he attempts to use his head or hands except in counting.

Testing Case VII. we find that he understands what is said; that he can read written and printed words; that he has the power of voluntary speech; that he can repeat after others; and that he can write and recognize objects. His articulation, however, is very bad; he is not easily confused, and when I ask him to sign this note he does so, but he tells me he would not do it if it meant anything; he is in every way responsible and competent.

Examining Case V. we have a different state of affairs. You remember she understands what is told her, but when I ask her how old she is she replies, "five cents." When I ask her to count *five* on her fingers, she says "three;" therefore she cannot repeat after me, and her pantomime is bad. She knows the use of objects, but mixes up the names. She is not letter-blind—that is, she can voluntarily read individual letters, and she can read her own signature; but she might be cheated because, although she can speak and can understand, yet she cannot make her wants clearly known, for the reason that she may have intended one thing and said another. In getting the mark of this person to an I O U she places it far away from the proper position. A case is on record where a man by pantomime showed how much money he wanted to leave to another, but he made his mark in the body of the will instead of at the end, and the will was not considered legal. It is dangerous to guide the hand of the person, because it might be construed as a form of compulsion, and the document would not hold in the law.

I have thus been able to show you a few of the kind of cases commonly met with, and to indicate the way in which questions of a medico-legal nature may arise. The subject is of interest, and could be more fully treated had we sufficient time at our disposal.

MEDICAL PROGRESS.

Multiple Bacterial Infection in Certain Forms of Diphtheria.—Dr. Wm. Royal Stokes (*Boston Med. and Surg. Journ.*, Dec. 12, 1895), in reporting the bacteriological examination of nine autopsies on cases of diphtheria treated with antitoxin, says: "In eight of the nine cases of uncomplicated diphtheria to which antitoxin had been given the bacteriological examination at the autopsy showed a more or less well-marked invasion of the blood by the pyogenic cocci. In five cases the streptococcus was found in the liver, spleen, kidney, and blood of the heart." The same or other cocci were discovered in one or more of the other organs in the remaining cases, while "in the lungs of all these cases were found the bacillus diphtheriæ, streptococci, pneumococci, and the staphylococcus pyogenes aureus, either alone or in various combinations."

The recent demonstration of the comparative frequency of this poly-infection in diphtheria is a matter of very considerable interest. Barbier and others, basing their conclusions upon the bacterial examinations of the throats alone, together with clinical observations, were able to point out the existence of two distinct forms of diphtheria as early as 1891; one the simple infection by the bacillus diphtheriæ, the other a mixed infection with one or more of the pyogenic cocci as well. Two years later the general belief that the bacillus of diphtheria was only to be found in the local lesion was disproven by investigations which demonstrated its presence in the blood and material taken from the various internal organs of individuals dead of diphtheria. And still more recently, Wright and Stokes have been able to discover it present in the lungs of thirty out of thirty-one cases, while the various other internal organs showed it less constantly, but in a considerable per cent. of that number.

So far as statistics of the double or multiple infection have been collected, they indicate that from fifty to seventy per cent. of the diphtheria cases are of this nature, at all events; a clear majority. And since antidiphtheritic serum is known to have no specific influence in controlling germs other than the bacillus diphtheriæ, we must not expect its full curative effect in these instances, but should be content to obviate the dangers of a secondary infection in any case by an early and thorough administration of the remedy.

The Etiology of Obstetrical Paralysis.—In a recent paper upon this rather obscure subject Dr. G. L. Walton, of Boston (*Journ. Ment. and Nerv. Dis.*, November, 1895), offered the following explanation of its causation: That the brachial plexus already being brought up against the clavicle by rotation of the head away from the affected side, which also places the suprascapular nerve upon the stretch, exposes these trunks to excessive bruising and stretching during the separation of the head from the shoulder, that follows rotation in the strait, the shoulders being naturally restrained by the brim of the pelvis at this stage of delivery. Under the head of obstetrical paralysis Dr. Walton did not wish to include any except those occurring with natural labors, *i.e.*, without instruments, or even the use of traction by hands or fingers of the attendant.

Dr. Starr, in discussion, expressed the belief that the prognosis was uniformly favorable, as he had observed no adults with such paralysis. Exclusive of those instances where there is dislocation of the shoulder-joint, Dr. Walton concurred in this opinion, while Drs. Taylor and Leszynsky had observed cases that caused them to doubt if a perfect recovery was the invariable rule.

A Case of Congenital Aphasia (Aphemia).—Herzen (*Revue Médicale de la Suisse Romande*, 1895, No. 11, p. 600) has reported the case of a boy, five years old, otherwise apparently in good physical and mental condition, who was able to speak only a few words. The family history was good, and there had been no difficulty in the labor or in the pregnancy. The child had escaped the usual infectious diseases. When three years old he could pronounce correctly only three or four words, which formed his entire vocabulary. At this time he fell from a table about three feet high, striking upon his head, but not suffering any permanent disturbance. Consciousness was lost, and it was feared that death would result, but recovery finally ensued, without paralysis or convulsion. Subsequently the little patient acquired a few new words, whose number and pronunciation, however, were below those of a child of his age. Examination disclosed a symmetrical head, free from fissure or depression. The organs of phonation were perfectly normal. The child could open its mouth and move its tongue freely; also emit sounds, and articulate several words more or less intelligibly; but it was unable to formulate any phrase whatever. Its hearing and its intelligence were good. There was no trace of paralysis or of atrophy. The child was right-handed. The explanation of the condition present in the case related is referred to a congenital malformation of the speech-centers in both central hemispheres.

Death under Chloroform.—Dr. Murray-Aynsley (*New Zealand Med. Journ.*, vol. viii. p. 259) reports this unfortunate accident having occurred to a healthy female who was admitted to Christ Church Hospital May 6, 1895. She gave a good family history, but was a little anæmic and had a slight goitre. For the removal of a ganglion on the back of the left wrist she was placed under chloroform at 9.45 on the following morning, and was well under before the operation was begun by Dr. Nedwill. The excision had been completed and the chloroform suspended, when the patient began to move a little and vomited a little bile-stained mucus. A few seconds later it was noted that she was cyanosed, but still breathing naturally and the lungs expanding. She was inverted, the throat sponged, and the tongue drawn out. The pulse, however, could not be felt. She was replaced on the table, took several gasping breaths, and after a few moments ceased to respire. Nitrite of amyl, ammonia, and strychnine were administered, and artificial respiration kept up for an hour, air entering the lungs freely during this time. For the first half-hour slight and irregular sounds were thought to have been heard over the region of the heart, but none during the latter half of the time. No autopsy was permitted.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . .	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

LEA BROTHERS & CO.,

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK, AND NOS. 706, 708 & 710 SANSOM ST., PHILADELPHIA.

SATURDAY, JANUARY 4, 1896.

THE MEDICAL NEWS BECOMES A NEW YORK WEEKLY JOURNAL.

WITH this issue THE MEDICAL NEWS removes its home from Philadelphia to New York and passes into the hands of a new editor. No other radical change has been made or is contemplated. The same familiar face will greet its readers every week, bearing its messages of scientific facts, of personal experiences, of recent discoveries, and of medical news. Messrs. Lea Brothers & Company, now of New York and Philadelphia, will continue as its proprietors and publishers. The editorial and publication offices are permanently established in New York. Dr. J. Riddle Goffe becomes the editor, and in so doing desires to express, in behalf of THE NEWS, a warm esteem for the retiring editor—a high appreciation of his unwearied and able services in the past.

THE MEDICAL NEWS, therefore, takes its place as one of the regular weekly medical journals of this city.

To you, our host of contributors and readers in every land, no new introduction is deemed necessary; but rather would we invite you, as tried and loyal friends, to join with us in a cordial housewarming in the new metropolitan home, where you will always be assured a hearty welcome and the same unwavering support in your efforts to advance the science and the art of medicine.

As an exponent and leader of what is highest and best in medical literature, THE NEWS will continue to advance the standard of hygienic and sanitary science, to voice the latest discoveries in every field of scientific investigation, and advocate all public measures that will redound to the health of communities and the public welfare. Its columns will be always open to the free and candid discussion of all questions pertaining to the advancement of medicine in its widest interpretation—to questions of interest and importance to the profession itself and to personal matters of individual right and justice. It does not represent any individual interest, nor school, nor clique, but aims to be an exponent of the highest and broadest interests of science and the medical profession.

The Science of Medicine is being rapidly revolutionized and rewritten, on what gives promise of being an enduring basis of scientific fact. The veil that has hidden from our view the mystery of diseased processes is being rent in twain, and a flood of sunlight is converting the workers of disease into manufacturers of antidotes against their own destructive powers.

It is the proud boast of the physical sciences that they have chained the great material forces of Nature and trained them to man's service. But the silent, secret microscopical forces working against man himself are the last to yield to his intellectual power. The triumph, however, is the greater and the glory is with us of the medical profession. It is a privilege to be in at the birth of what promises to become the crowning achievement of medical science and an unspeakable boon to humanity.

To test and extend the application of the new therapeusis is the work of the immediate future, demanding the accurate application of exact scientific methods. To the general practitioner is committed the trust, to him the scientific world looks for the account of his stewardship; and it is to him especially that the columns of THE MEDICAL NEWS are cordially opened as the most appropriate place for recording his triumphs, deductions, and conclusions.

Yet, after all, this is but one of many fields in which the physician and surgeon are constantly at work to relieve the sufferings of humanity. THE

MEDICAL NEWS will, as heretofore, be ever on the watch to present to the profession all the discoveries and improvements which may be made in all the departments of the science. It can point to fifty-two years of earnest service rendered to all the highest interests of the medical profession, and it will be the unswerving purpose of the new editors to surpass, if possible, this honorable record by the diligent utilization of the superior advantages of their metropolitan position.

THE STATE COMMISSIONER OF LUNACY.

THE Commissioner of Lunacy as an expert was editorially noticed by the *Record* recently, which goes on to say that "attention has been called more than once to the reprehensible conduct of the medical member of the State Commission in going upon the witness-stand for pay. That he has no right to do so in this State cannot be disputed, for his testimony in court, when it is given by him as an 'expert,' may send the prisoner to an asylum or a prison. As the doctor and his associates are bound by law to recommend the discharge of improper subjects from the former, it can be seen how dangerous must be his position if he has given testimony in a particular case." Just so. And see what has happened within less than a month. He took the stand and declared Hannigan insane. Within two weeks, so remarkable was recovery, the Commission was asked to discharge the man. Yet how could it do so in the face of the testimony so recently given. The courts were appealed to.

Judge Barnard refused to order the discharge of the prisoner from the State Hospital, and insisted that the indorsement of the State Lunacy Commission to the certificate of sanity given by the superintendent of the hospital is needed to make Hannigan's discharge legal.

He says that when a man is acquitted of the crime of murder on the ground of insanity, and then committed to an asylum, three processes are needed to secure his discharge—viz., first, the certificate of the superintendent of the asylum; second, the indorsement of the State Lunacy Commission; and, third, an inquiry by a Supreme Court Justice as to the man's sanity. He could not understand, he said, why the Lunacy Commission refused to indorse the certificates of Dr. Pilgrim. He remanded Hannigan back to the asylum.

Immediately after Judge Barnard declined to discharge Hannigan from the hospital his lawyers went to Newburg. There they found Justice Brown, and renewed their application for a writ of habeas corpus for their client. Judge Brown signed the writ. He was unwilling, however, to hear arguments on the case that day, though the officials of the hospital had taken Hannigan to Newburg immediately.

The Commission was appointed to save the taxpayers of the State, not to furnish means for useless expenditures. The detention of the superintendent, the various keepers and attachés in attendance at court—first in Poughkeepsie, then to Newburg—was a waste of public moneys and a perversion of principles. The Legislature should speedily amend this section, for what was a few days ago only a theory, to-day becomes a burning shame.

WHICH DOES IT ADVERTISE?

THE above question is irresistibly suggested by a glance through a bulky pamphlet recently issued in Chicago by the manufacturer of one of the many concentrated foods which glut the market. It is the stale and familiar compound of "original research," reports by the hired chemist of the firm or by similarly "influenced M.D.'s," who usually sign themselves as third or fourth assistants to some distinguished hospital or clinic, with testimonials from various physicians and "professors," deftly interspersed with insinuating and laudatory remarks by the head-salesman. All of which has the impudence to call itself "scientific matter," and claim to be latest views upon the problems of nutrition, "condensed for the benefit of the busy practitioner," who is expected to be duly grateful therefor. And the agents who distribute these actually assume the airs of benefactors and enlighteners of a poor, benighted profession. A very brief inspection of this particular hodge-podge, however, reveals the fact that, like a "double" Uncle Tom's Cabin, it exploits "two Topsies," and that the burden of its song seems to be divided between "the product" and its "developer," a certain doctor of our own city (to our shame be it said) whose name and titles adorn its columns in reckless profusion, occurring ten times in the first twenty pages. This apotheosis begins in the introductory chapter, where he is hailed as the genius who developed new methods of application . . . . of this power" . . . . "up to the marvellous scope and efficacy now exhibited by his reports, which *make up the marrow* of these pages." Not

the marrow merely, but the periosteum also and part of the Haversian systems, for his name appears at the foot of articles, at the head of them, in the middle of case-reports, and even in the ignominious ruck of testimonials from the wilds of Arkansas and the cross-roads of "Injianny." In fact, it seems to be a contest between the Doctor and the food, with the odds in favor of the Doctor; for while he achieves the proud literary feat of mentioning the food by name *eight* times in a single page of "contribution," yet it gets only a plain capital, while his name looms up majestically in double capitals, with its titles trailing behind it like the lurid tail of a comet, clear across the page. This is by no means the first time that a physician has endeavored to waft himself into prominence on the wings of a proprietary remedy, but it is such a glaring and disgusting instance of the offence that it merits special mention. Its very grossness, however, defeats itself, for it is so palpably overdone that it raises the question, Who pays for the advertisement, the manufacturers or the Doctor?

Another amusingly impudent feature of this pamphlet is the insertion of the names of distinguished clinicians, in staring capitals in the middle of pages loaded with resounding praises of the aforementioned food, which names, however, on careful inspection, are found to be simply appended to some trite commonplace as to the value of nutrition, the uses of proteids, etc., with no reference to the food whatever. It reminds one decidedly of the late Artemus Ward's lecture-prospectus, which read somewhat as follows:

"MR. WARD HAS DELIVERED THESE LECTURES BEFORE ALL THE CROWNED HEADS OF EUROPE ever thought of delivering lectures."

OUR CHANGE OF HEART.

THE *Medical Record*, in commenting upon our removal to New York, interprets it as evincing "a sudden change of heart." We beg to submit that this is not a sudden change of heart, but simply a change of base.

To hold the affections subordinate to the reason is recognized as a safe rule of conduct, and it is in obedience to this that this Journal, after a careful consideration of all the factors in the situation, finds itself irresistibly drawn to New York. We are far from admitting, however, that the kindly consideration of our esteemed contemporary may not draw our affections after us, and lead us to experience the realization of the old saying, that where our friends are there will our heart be also.

ECHOES AND NEWS.

CORNELL girls have successfully withstood two sessions of vivisection without any marked increase in hysterics or nervous diseases. All students at Cornell are required to dissect during a part of their freshman or sophomore year.

THE foundlings of New York hereafter will be sent directly to Bellevue Hospital. It has been learned that under the present rule, whereby such waifs are first taken to Police Headquarters, at least eighty per cent. die of exposure and hunger.

THE pre-trial system, so extensively used by the governments of Germany and France, has been advocated by the chief expert to the New York City District Attorney's office, and its workings are being carefully watched in a series of cases. There will, under the new system, be no convictions of insane men, and fewer sane men will be able to escape on the plea of insanity.

A SPECIAL MEETING OF THE NEW YORK ACADEMY OF MEDICINE was called on the 27th ultimo to consider resolutions of censure for the Commissioners of Charities and Correction in their recent action in placing the appointment of physicians and surgeons to the various hospitals in the hands of the three principal medical colleges, together with the fourth division of Bellevue Hospital.

After a prolonged discussion the resolutions were *not* sustained, the vote standing 47 to 108.

THE danger of blood-poisoning in piercing the ear is not to be ignored because the operation is supposedly not a dangerous one. There is nothing right about this home surgery. The cleanest person, when it comes to a surgical operation, is, without proper scientific laving, medically unclean. A woman takes a needle, any needle, and threads it with any thread. This thread may have been in her work-basket months and months, lying next to other spools of all colors. She would not think of washing her own hands or washing the ear to be pierced. A cork is taken out of some bottle, any bottle, without thought as to what is in the bottle or how long the cork has been exposed to the dust. This cork is placed under the lobe of the ear for the needle to strike against when it comes through. Inflammation and suppuration naturally result.

IT is reported that Dr. Cæsar Lombroso has just been convicted in a French court of gross plagiarism, and condemned to pay the man out of whose book he stole the sum of 2500 francs. The plaintiff, M. Crepieux-Jamin, found in *La Grafologia*, a work by Lombroso, published at Milan, passage after passage which were simply translated from a book by M. Jamin, to whom no credit was given, and whose name was not once mentioned by this soi-disant criminologist. He brought suit at Rouen under the International Convention adopted at Berne, in 1844, and won a verdict without difficulty, the evidence being indubitable. A tendency toward plagiarism, we have been told by both Lombroso and Nordau, is a sign

of degeneration. Doubtless it is—degeneration of the conscience.

There will be held at Washington, D. C., on February 10, 1896, a competitive examination of candidates for appointment to the position of Assistant Surgeon in the U. S. Marine-Hospital Service. Candidates are required to be not less than twenty-one or over thirty years of age. They must be graduates of a reputable medical college, and furnish testimonials as to character.

Successful candidates, having made the required grade, are appointed in order of merit as vacancies arise during the succeeding year. There is at present one vacancy.

A successful candidate when recommended for appointment is commissioned by the President of the United States as an Assistant Surgeon. After four years of service, and a second examination, he is entitled to promotion to the grade of Passed Assistant Surgeon, and to the rank of Surgeon, according to priority, on the occurrence of vacancies in that grade.

The salary of an Assistant Surgeon is $1600 per annum, together with furnished quarters, light, and fuel; that of a Passed Assistant Surgeon $1800 per annum; and that of Surgeon $2500 per annum. In addition to the above salaries, after five years' service, an additional compensation of ten per cent. of the annual salary for each five years of service is allowed medical officers above the rank of Assistant Surgeons, the maximum rate, however, not to exceed forty per cent.

When an officer is on duty at a station where there are no quarters furnished by the government commutation of quarters is allowed at the rate of $30 per month for an Assistant Surgeon, $40 for a Passed Assistant Surgeon, and $50 for a Surgeon. The successful candidates after receiving appointments are usually ordered to one of the larger stations for training in their duties.

Full information may be obtained by addressing the Surgeon-General of the Marine-Hospital Service, Washington, D. C.

The Remedies of Animals. From the earliest ages animals have been credited with a considerable knowledge of the medical properties of plants. Legund relates that Esculapius cured a patient by using an herb which he had seen a sick goat search for and eat. In the Middle Ages systems of therapeutics (bestiaries) were founded upon reported animal practice, just as to-day the populace confide implicitly in the sovereign virtues of Indian "blood-medicines," and Chinese, negro, or gypsy "roots" or "herbs." A writer in the London *Spectator* gives a most elaborate and interesting list of the remedies reported to be used by animals for either the cure or prevention of disease. Grouse, for instance, during an epidemic of bird-plague, have been known to fly down to the seashore and eat the salt-crystal evaporated upon the rocks. Pheasants scratch up and eat the roots of the wild arum, which are so pungent as to blister the tongue, and also the colchicum-root, presumably as aromatic digestives; at all events pepper and other spices must be added to their food when domesticated. Quite a variety of substances are eaten apparently mainly for their mechanical effect as emetics and purgatives by the carnivora. This is the rationale of the familiar use of grass by dogs and cats, also by lions, tigers, and leopards, and of ashes or dirt by dogs fed largely from dishes or upon cooked foods. Our author also adduces the fondness of ruminants for salt and of birds for grit and gravel as cases in point, but these come distinctly under the head of diet and normal aids to gizzard-digestion. The same sort of objection applies to the great variety of water, dust, and mud-baths given by him, though, so far as the last two are directed against parasites, they may be regarded as remedies.

Indeed, the impression decidedly given by a careful study of the whole list is that the actual amount of really "medical" knowledge possessed by birds and animals is very slight, as would naturally be expected in view of the absence of any form of language adequate to transmit the knowledge of one generation to the next. Disease is such an infrequent and irregular factor in animal welfare, leaves such comparatively slight permanent imprints upon either mind or body when mild, and none at all, of course, when fatal, and is so very seldom inherited, that it is hard to imagine how "remedial" instincts of any sort could well be transmitted, while the amount of therapeutic knowledge directly acquired during the brief lifetime of an individual must be very limited. Speech is absolutely necessary for the transmission of any but the most rudimentary forms of knowledge. In the realm of surgery and external applications birds and animals make a somewhat better showing, because parasites and wounds or other injuries play a much more frequent and constant part in their experience, and hence some rude idea of their treatment can both be acquired by the individual and transmitted so as to be acted upon by natural selection.

And yet even here it seems to be largely a process of using the first application that comes to hand. Nearly all birds and animals use dust-baths or mud-baths of some sort to protect themselves against vermin, and some are said to exercise a choice between different sorts of mineral-laden earths. Sea-birds are said to seek fresh water to bathe in. The dog in particular and carnivora in general cleanse and soften their wounds by licking until a sort of plaster forms over them, composed of saliva, hair, and dust. The elephant blows dust from his trunk over his surface-wounds, or covers them with mud, and even plasters up bullet-wounds with the same materials. He will also cover his sun-scorched back with cool green leaves. Tradition declares that the pig is the original inventor of the mud-bath—which seems tolerably obvious—and that several of the mineral-springs of Europe were discovered by the swine-herds whose pigs resorted to them for the cure of skin eruptions or diseases. The famous waters of Bath are said to have been brought to human notice in this way by the swine of Prince Bladud. Nowadays such things are done by syndicates—which is much better. In fact, animal medicine and surgery are at best extremely primitive and blunted, and most of widespread popular beliefs to the contrary are either superstitions or due to misunderstandings. The fondness of cats for catnip, for instance, is solely due to the similarity of its odor to the feline genital secretions. The mongoose does not depend on an herb to cure him of cobra-bite, but upon his extraordinary agility and skill in avoiding the snake's stroke, and most such "cure" and "antidote" stories have little better foundation.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, December 19, 1895.

JOSEPH D. BRYANT, M.D., PRESIDENT.

VAGINAL VERSUS ABDOMINAL SECTION IN DISEASES OF THE FEMALE PELVIC ORGANS.

DR. W. M. POLK read a paper with this title. (See page 2.)

DISCUSSION.

DR. E. W. CUSHING, of Boston, opened the discussion. He said that there could be no longer any doubt in the minds of those who had studied the evolution of vaginal hysterectomy that the resources of our art had been wonderfully increased by the introduction of morcellation of the uterus, and it was very significant that in the face of opposition the method had steadily increased in popularity, until now it numbered among its advocates some of those who at first had most bitterly opposed it. There were still many, however, who believed with an eminent surgeon in this country that vaginal hysterectomy for pus-tubes was "blind, ignorant, and cowardly." The question at the present time was really between total abdominal and total vaginal removal of the uterus and appendages. By splitting the uterus in half the organ could be brought down much further, and by successively dividing these halves it could be made to descend gradually and rotate anteriorly, thus bringing into view any adhesions that might exist. Clamps were applied to the vessels of the broad ligament under the guidance of both sight and touch. By this method of operating the uterus could be safely and quickly extirpated, even when bound down by firm adhesions, and fibroids up to the size of a cocoanut could be removed with far less shock than by abdominal section. The simplicity of this method and its comparative freedom from danger could hardly be believed by one who had not had the opportunity of seeing it done by an expert. If the tubes are full of pus, they may be opened and washed out without soiling the peritoneal cavity. Want of space between the ischia and a tumor over five inches in diameter are serious contraindications to the vaginal operation, and where there are many adhesions to the intestine one not thoroughly familiar with the vaginal route should not attempt to operate by this method. It was generally accepted, the speaker said, that the vaginal operation was best in the severest cases—those in which there are large purulent accumulations from tubo-ovarian abscesses, or from suppurating hæmatocele where the pus is roofed in by dense adhesions of bowel and omentum. When it is not certain that both appendages are involved the vaginal vault can be opened behind, or, still better, anteriorly, and the question of the removal of the appendages determined by inspection. The advantages of the vaginal operation were diminution of shock, freedom from abdominal wound and scar, and from the liability to hernia.

DR. CUSHING then projected on a screen a large number of photographs taken during a vaginal operation, and exhibiting the various steps in the technique, as well as the facility with which the uterus and associated tumors could be brought into view and carefully examined.

DR. W. T. LUSK said that it was particularly interesting to hear from Dr. Polk on this subject, as he had been the pioneer in this work in this city. When it had been proposed in Brussels, in 1892, to substitute the vaginal route for the abdominal method in doing much of our work, the speaker said that he had received the suggestion with impatience, but his attention had been called to the method by the great rapidity of convalescence of patients operated upon by the vaginal route, and he had at last become a convert to the vaginal operation. The capabilities of the method had been strikingly demonstrated to him by a personal observation of the work of such surgeons as Péan, Pozzi, Ségond, and Jacobs. Notwithstanding the length of time required for the removal of fibroids by the vaginal route by morcellation, it was worthy of note that the operation had scarcely an appreciable effect on the patient. In cases of double pyosalpinx, in which the uterus was removed first and the tubes afterward, the vaginal method was certainly safer than the abdominal. He had hesitated longest about employing the vaginal route in cases in which it was desired to do conservative surgery on the appendages, and he still thought that the abdominal route was the better for this class of cases except where a free anterior incision was employed. By the latter procedure it was usually possible, if the tubes were not greatly enlarged, to detach the tubes, and bring out first one cornu, then the fundus, then the other cornu, and lastly the tubes. There was no more shock attendant upon this procedure than followed ordinarily an amputation of the cervix. On its merits alone, he would say that the vaginal operation was the coming method, but there was another reason, and that was that the women were beginning to insist that they should be operated upon in this way. In closing, the speaker cautioned those who wished to change to the vaginal method to go slowly, and select for a trial of this method only the simpler cases. He felt sure that these vaginal operations would be followed by much less discomfort to the patient.

DR. J. M. BALDY, of Philadelphia, said that he believed he was almost alone here in opposing the vaginal operation. He had no quarrel with the beauties of the vaginal method, nor did he question many of the advantages and results, but he felt that the two routes had not been compared with sufficient care. He was positive that there was as little shock after the abdominal operation as after the vaginal operation, and also that the peritoneal cavity was opened almost as frequently by the vaginal route. He also contended that it was infinitely more reliable to operate through the abdomen with the patient in the Trendelenburg position than to operate by the vaginal route, because in the former one had the aid of both sight and touch, and was in a much better position to determine whether an operation should proceed further or terminate as an exploratory incision. In comparing the two methods of operating, great stress was laid upon the very slight degree of shock observed after the vaginal operation; but in his experience shock was not a great element in pelvic surgery. To be sure, the pulse often became weak after the operation, but this was usually due to the withdrawal of the ether. Another common argument of the advocates of the

vaginal operation was that hernia was avoided. Hernia after abdominal operations was now comparatively rare and was perfectly amenable to proper and timely treatment; moreover, a number of cases of hernia following vaginal hernia had already been reported. Any surgeon would agree with him that a vaginal hernia was much more difficult to treat than an abdominal hernia. The bright side of the vaginal method had been very ably presented, but nothing had been said about the alarming proportion of fistulæ following this operation. Most operators by the vaginal route had included fifteen or twenty cases of fistulæ in their lists of these oprations, and many of them had spoken of the difficulty of curing them. Sometimes an abdominal operation was demanded for the relief of this serious complication of the vaginal operation. Injury to the ureters was not at all uncommon, and by the vaginal method the operator was ignorant of the existence of the complication. Three times in his own experience he had injured the ureters in abdominal operations and only discovered it just in time to rectify the difficulty.

One of the great objections to the vaginal method was the incompleteness of the operations. He had never seen a vaginal hysterectomist do a complete operation. As an expert operator required nearly twice the time to operate by the vaginal route as by the abdomen, this prolongation of the etherization was a matter for serious consideration. Nor could he accept the statement so persistently made, that convalescence was much quicker after the vaginal operation. The abdominal operator believed that his patient was better off in bed for four weeks after the operation, irrespective of her recovery surgically; the vaginal hysterectomist allowed his patient up as soon as she was surgically well. After considering all these arguments, and duly weighing them, he was free to confess that in his opinion the balance was in favor of the abdominal operation, sentiment not considered.

DR. E. B. CRAGIN said that the first vaginal cœliotomy he had ever seen had been done by Dr. Polk, and the more he saw of vaginal work the better was he pleased with it. All surgeons must have noticed a certain depression of the patient after abdominal operations, and without stopping to consider whether or not this was shock, he would say, further, that all must have noticed also that this depression was not so great after the vaginal operation. He could not agree with Dr. Baldy in excluding from the cases suitable for vaginal operation large pelvic intraperitoneal abscesses. These were exactly the cases in which the vaginal operation showed its superiority.

Since March 2, 1895, he had performed 55 vaginal cœliotomies, of which 42 were for diseased appendages. According to his experience, therefore, about 75 per cent. of cases of diseased appendages were suitable for the vaginal operation, and the remainder for the abdominal operation. He believed that there was more danger of injuring the rectum in the vaginal operation, yet, as Dr. Baldy had said, the ureters were likely to be injured in abdominal operations. He believed that the vaginal operation gave better results, both immediate and remote, and that vaginal hysterectomy was an operation that had a future.

DR. CHARLES P. NOBLE, of Philadelphia, said that the arguments in favor of the vaginal route had been presented, but everything had been stated in very general terms. He would like to ask Dr. Polk and Dr. Cushing how many vaginal operations they had done, how many deaths they had had, and how many fistulæ they had met with.

DR. POLK replied that his mortality had been 3 in 72, and the fistulæ 2 in 73.

DR. CUSHING said that he had had about 75 vaginal hysterectomies, with 5 deaths; and of this number there had been 2 urethral fistulæ and 1 fistula of the bladder, all of which had been cured. In a recent series of cases there had been 20 vaginal operations, with 1 death. All his operations had been complete.

DR. NOBLE said that in comparing the two methods of operating one should consider the mortality, the morbidity, the sequelæ, the mode of convalescence, and the ability to deal with complications. The mortality was very low by both methods, although it was somewhat less by the abdominal method. It depended chiefly upon the operator. The morbidity after abdominal operations was not more than 5 per cent. in his experience. Adhesions occur with both methods. Most operators reported about 10 per cent. of incomplete vaginal operations, which should be contrasted with the small number of infected pedicles in the abdominal method. He thought that there was but little doubt about bowel and bladder fistulæ being more frequent after the vaginal operation. His own cases of vaginal hysterectomy had been in hospital as long as the abdominal hysterectomies; in fact, he thought convalescence was more rapid after the abdominal operation. By the abdominal route, in his opinion, it was far easier to cope with complications arising during the operation, and also to control the hemorrhage. The use of clamps to arrest hemorrhage was at best very crude surgery. As he had recently reported 200 cases in which the abdominal wall had been united with buried silkworm-gut sutures for the relief of hernia, and without a single relapse, the argument that the abdominal operation should be avoided because of the frequency with which it was followed by hernia should have but little force.

Where the facilities in a hospital for securing asepsis were poor he would prefer to operate from below. He was prepared to believe that by anterior colpotomy one could remove small fibroids, but for larger tumors he would greatly prefer abdominal section to the vaginal operation with morcellation. He would likewise prefer the abdominal route in dealing with tubal pregnancy, except in the few cases in which there was a suppurating hæmatocele. The operation from below was likely to result in the unnecessary sacrifice of ovaries in this class of cases.

He did not wish it to be understood that he was opposed to all operating through the vagina, but he would reserve this method for cases of large pelvic abscess, and where the women were very fat.

DR. H. J. BOLDT said that his conclusions regarding the comparative advantages of the two methods had been formulated only after a large experience with both abdominal and vaginal operations. The vaginal operation was applicable to tumors of considerable size, provided the neoplasms were movable, to cases of tubal pregnancy before rupture, or after rupture and cessation of hemorrhage, and to fibroids which did not extend more than three or four fingers above the symphysis.

The submucous and interstitial fibroids were most successfully treated in this way. For other fibroids, and for neoplasms in virgins, he considered abdominal hysterectomy preferable. It was quite possible to do a complete operation in nearly every case by patient and careful work. The risk of injuring ureters and bowel was about the same in the two methods. He had never seen a vaginal hernia. While admitting the possibilities of the vaginal method, he felt that a more satisfactory diagnosis could be made by a free abdominal incision.

DR. H. N. VINEBERG said that he was among the first to introduce the operation of vaginal incision, which was the forerunner of vaginal section in conservative surgery. He had reported several cases last March. His experience was entirely opposed to the view that the tubes and ovaries could be resected more satisfactorily by the abdominal route. The vaginal operation was particularly appropriate to these cases, because they were often associated with retroversion, a condition which could be readily relieved at the same time by sewing the uterus to the vaginal wall. He could not see that Alexander's operation offered any special advantages over anterior vaginal fixation.

DR. PAUL F. MUNDÉ said that the discussion thus far was calculated to convey the impression that all the New York surgeons had been converted to the vaginal procedure, which was far from the truth. He had extirpated the uterus per vaginam for cancer 27 times with 24 recoveries, but as he had secured just as good results, and more easily, by the suprapubic route, he would not care to employ the vaginal method in these cases hereafter. There was certainly no more shock following the abdominal section. As was well known, he was not given to operating frequently on fibroids, but out of the 33 abdominal hysterectomies that he had performed for this condition, 4 had died. The abdominal operation was certainly easier than the vaginal. He had long maintained, and in the face of much opposition, that all fluid accumulations were best operated upon through the vagina, and he was glad that this method now had an increasing number of advocates. He would limit the vaginal operation to cases of pelvic abscesses in which the vagina was roomy and the sacs could be drained or enucleated.

DR. E. E. TULL exhibited a specimen to demonstrate the completeness of the vaginal operation. He had done 50 operations of this kind with 2 deaths. These deaths were due to purely accidental causes. He could not understand why some surgeons used so many clamps and ligatures. He had recently removed a tumor weighing ten pounds, and in this operation had used only one clamp and two ligatures.

DR. W. GILL WYLIE said that although he had done about 1500 abdominal sections he had resorted to the vaginal route only 100 times. Out of these 100 vaginal hysterectomies there had been only one fatal case, and he attributed his excellent results largely to the fact that these vaginal operations had been done in a favorable class of cases. The abdominal method was assuredly the one admitting of more general application, and if the great surgeons of France had been as expert in abdominal surgery as the American and German surgeons he was of the opinion that the vaginal method would not have been so strenuously advocated.

DR. POLK, in closing the discussion, said that there seemed to be a general agreement regarding the greater simplicity of the abdominal route, and although it was a general rule that the easier the operation the better the work done, this proposition did not hold good if in attaining this ease of operation it was necessary to do violence to important structures. The peritoneal cavity was just as likely to be opened in the one method as in the other. When the time consumed in suturing the abdomen was considered, it was evident also that there was no very great difference in the time occupied by the two operations in a given case. He had made no mention of cancer in his paper because he was not decided as to which operation was the better one. He was inclined to think, however, that we were justified now in performing abdominal section, and in adding to the old Freund operation the removal of the broad ligament and of infected glands.

It so happened that those who had participated in this discussion had not grasped what he considered the great underlying principle, viz., that peritonitis usually originates in the lower part of the pelvis in close relation with the vagina, and that by early incision into this structure it was possible, with little or no risk to the patient, to cut short diseased processes and save important structures in the pelvis. Having once adopted this practice of early operative interference by the vaginal route, he felt confident that all the objections that had proved such stumbling-blocks in this discussion would be forever wiped away.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting December 3, 1895.

EDWARD D. FISHER, M.D., PRESIDENT, IN THE CHAIR.

GRAVES'S DISEASE—ŒDEMA OF THE EYELIDS.

DR. J. ARTHUR BOOTH presented a case of Graves's disease with the presence of a rather rare symptom—œdema of the eyelids. On inspection the diagnosis of Graves's disease had been made, but the examination had revealed no exophthalmos. There was, however, slight enlargement of the thyroid and a rapid pulse. The patient, a girl, aged seventeen years, was very much frightened when quite young. She had some convulsions following this incident. About the time of her first menstruation œdema of the eyelids first appeared. She now complained of palpitation of the heart, profuse sweating, headache, and general weakness. This œdema, the speaker said, was not a true œdema, as it did not "pit" on pressure. The movements of the lids were harmonious. On palpation swelling and diffused hardness of the thyroid could be made out. When seen about one month later, *i. e.*, December 2d, there was apparently a slight prominence of one eyeball. Four examinations of the urine had been made, but nothing abnormal discovered.

CEREBRO-SPINAL SYPHILIS.

DR. CHRISTIAN HERTER presented a young man, aged twenty-eight years, who gave a history of having had a chancre two years ago, and about one year thereafter developing various cerebral symptoms. The vision was first observed to become diminished in the right eye; then there was ptosis on that side, paralysis

of the third nerve, paralysis of the facial nerve and of both trigeminal nerves. After this he developed weakness in certain muscles of the right arm. There was a history of rheumatism in the parents, and of alcoholism in the patient. About one year ago there was a purulent discharge from the left ear, which lasted for several months. One year ago the right eye was struck by a piece of hoop from a barrel. Shortly afterward he began to complain of double vision, and saliva drivelled from the right angle of the mouth. There had been at no time pain in the hand or forearm. Under the administration of iodide the patient had regained some control of the movement of the eye-muscles and right eyelid. The physical examination, on November 26, 1895, showed the man to be small and fairly nourished, with lateral curvature of the spine, and considerable deformity of the thorax. There was slight ptosis on the right side. The right internal rectus was extremely weak, and there was paresis of the superior and inferior recti. There was sufficient power in the internal rectus to maintain binocular vision, but not sufficient to preserve convergence. The reaction to accommodation was greatly impaired. R. V. was 20/50, and L. V. 20/40. Both optic disks were found to be distinctly paler than normal, and the vessels slightly narrowed. Near the right disk were two patches of slight choroidal atrophy. All the movements of the face were well performed, and there was no drivelling of saliva. Reaction of the facial muscles to faradism was well preserved. The temperature-sense and tactile-sense presented fairly well-defined areas. Sensation was preserved over the eyelids, and was only moderately impaired over the nose. Near the lips sensations of pain and touch were slightly impaired. The uvula deviated to the left. The sense of taste did not seem to be distinctly impaired. There was some loss of power in both arms, but this was more marked on the right side. The flexors of the right wrist were weak, and those of the fingers were wholly paralyzed. The power of the pronators and supinators was normal. All the paretic and paralyzed muscles were wasted. All the paralyzed muscles showed the reaction of degeneration to a greater or less degree. The ulnar area of the right hand and lower two-thirds of the forearm showed loss of sensibility to pain, temperature, and touch. In the left hand and forearms there was a moderate loss of power in the flexors of the fingers. There was no wasting of the left forearm or any change in sensibility or electrical reaction. In both arms there was slight and rather coarse tremor when the arms were extended. There was no loss of power in the legs, and sensibility was not impaired. Both knee-jerks were absent, but the plantar and cremasteric reflexes were present. There was considerable oscillation on standing with the feet together and the eyes closed. The patient urinated without straining. There was frequent pain in the right hypogastric region, but no "girdle" pain. There had evidently been marked improvement during the past month under the use of iodide. The conditions present in this patient were undoubtedly due to the lesions of cerebro-spinal syphilis. The fifth nerve had been more damaged than the others.

The speaker said that the two points upon which he desired further information were: (1) The exact location of the lesions at the base; and (2) as to whether or not the patient has locomotor ataxia.

DR. W. M. LESZYNSKY said that he recalled having seen a man, aged about fifty-eight years, with very marked exophthalmos and goitre, associated with marked œdema of the eyelids. This œdema, however, had been absent in one eyelid for a time, and it had gradually disappeared.

DR. B. SACHS said that within the last few years he had seen upward of thirty cases of Basedow's disease, and yet he had never observed such œdema in any of these cases.

DR. J. ARTHUR BOOTH said that he had been unable to find any mention of more than one case of the kind in English literature. It was interesting that no exophthalmos had been noticed until a few weeks ago. It had been suggested that the œdema was due to paralysis of the orbicularis.

DR. SACHS said that he agreed to the diagnosis of cerebro-spinal syphilis in Dr. Herter's case, but would prefer to have it called *multiple* cerebro-spinal syphilis. The involvement of a large number of cranial nerves and imperfect involvement of some of these nerves were especially characteristic features. He had made the diagnosis of cerebro-spinal syphilis several years ago in a case in which there had been complete trophic paralysis of the upper and lower extremities, with ptosis. One critic had looked upon this case as one of neuritis rather than of central disturbance. This view he did not accept, for we had only to suppose that the specific meningitis had extended along the ventral surface of the cord instead of laterally to explain the symptoms. The fact that there had been improvement in some of the symptoms under the use of iodide was, of course, very significant. In his opinion there was no one symptom of greater value than the complete immobility of the pupil to accommodation and light, or the equal impairment of both of these functions. This was very different from the Argyll-Robertson pupil. If in addition to this there was a multiplicity of lesions, the probability of syphilis was very strong. He would not think of making the diagnosis of tabes in this case, because there was absence of the Argyll-Robertson pupil, little or no pain, and no involvement of the bladder.

DR. HIRSCH said that he did not think we could exclude general paresis of syphilitic character. The expression of the face, the tremor, and slight deviation of the tongue, all pointed toward this condition, and the diagnosis could not be made without further knowledge of the psychical symptoms.

DR. HERTER said that from his short acquaintance with the patient he felt that the psychical symptoms usually observed in general paresis were not present. His mental condition and memory were quite good, and his slight imperfection in articulation seemed to be due to an imperfect co-ordination of the lower speech-mechanism. The expression of the face appeared to be due to the ptosis.

THE PRESIDENT said that he would certainly agree with the diagnosis of cerebro-spinal syphilis, and also regarding the points of localization at the base of the brain.

DR. IRA VAN GIESON said that he wished to indorse the term "multiple" cerebro-spinal syphilis from a pathological standpoint. Syphilis of the nervous system should be considered in three forms: (1) The multiple variety appearing in the form of plaques; (2) the form

in which there were discrete gummata; and (3) the form in which there were less tangible lesions of the blood-vessels and interference with the nutrition of the blood-vessels.

DR. SACHS said that through recent researches the end-arteritis of the spinal cord had been very definitely established. The specific endarteritis of the cerebral vessels had been recognized for a long time, but more recently it had been very definitely established in some of the cases of spinal syphilis that there was a specific endarteritis of the vessels of the spinal cord with areas of softening in the cord. The speaker said that a few years ago he had been inclined to consider these cases as examples of meningeal infiltration, extending in gradually through the entire cross-section of the cord.

THE PRESIDENT said that most of the symptoms of general paresis were of later origin than those present in the case under discussion. This patient had already shown improvement, therefore the symptoms must be due to specific infiltration at the base of the brain, and also possibly to softening in the cord from an endarteritis —a condition shown to exist many years ago. This was essentially different from the chronic condition present in general paresis.

DR. A. WIENER presented a

REPORT UPON A CASE OF PROGRESSIVE MUSCULAR DYSTROPHY,

with the idea of showing that such a case could be improved by treatment. From a review of the literature, he said that it was apparent that the tendency now was to bring the disease formerly divided into spinal and myopathic forms under one head. The patient to be presented this evening, he said, had been exhibited two years ago before this Society. At that time he was twenty years old, and had been perfectly healthy up to May, 1892, and had not experienced the slightest difficulty in performing any muscular movement. The first indication of difficulty was in May, 1892, when he began to suffer from vague pains in the region of the spleen and liver on considerable muscular exertion. Shortly after this, difficulty in going up stairs and walking was observed, and soon atrophy of the lower extremities and back followed. Finally, the muscles of the neck and face became involved. The patient denied alcoholism or syphilis, and stated that his health had been excellent. He had noticed while engaged in athletic sports that the muscles of the upper extremities quickly became fatigued. In 1893 there was no distinct abnormality about the formation of the skull. His general appearance was that of a person very much emaciated, and there was great difficulty in walking and lifting the limbs. On attempting to stand upright he exhibited a marked lordosis. When lying down it was impossible for him to turn over. The muscles were soft and covered with redundant skin. No vasomotor or trophic disturbances were discovered. The deep reflexes were absent on both sides. The spinal column was in no way tender on percussion. Examination of the muscles showed a marked paresis. The muscles of the forearm and hand appeared normal. Mechanical excitability was very much diminished. Electrical examination gave quantitative changes, but no reaction of degeneration. The abdominal muscles were only slightly affected. The orbicularis oris and palpebrarum were the ones chiefly affected about the face. The deltoid muscle showed simple atrophy of the muscular fibres, with cell-infiltration in the muscle and between the fibres. No hypertrophy of the fibres could be found, and there was no evidence of fatty deposit. The small bloodvessels were filled with blood, and the walls with round cells. The lack of all sensory disturbances left no doubt that this was a case of the myopathic type. No improvement was noticed under the usual tonics and electrical treatment, so it was decided to try the effect on physical culture carried on daily to the point of exhaustion. From half an hour to one hour was devoted to exercises with dumb-bells, Indian clubs, and the use of a health-lift machine. There was evidence of a very marked improvement in every way. Quite lately he had been able to ride forty miles in one day on a bicycle. Some of the muscles still showed atrophy. The improvement was especially marked in the muscular movements and in the partial return of the contour of the parts. The speaker said he did not think such treatment would be efficacious in cases developing in infancy, but where there had been a good development prior to the appearance of the disease this plan of treatment offered a good prospect of success.

DR. G. M. HAMMOND said that the heart-symptoms in this man were very much like those seen in individuals who had received too much physical exercise at a time when the heart was feeble. This man's heart was dilated and hypertrophied, and it was possible that this was due to a loss of muscular tissue as a part of his disease. He asked if Dr. Wiener thought the arrest of the atrophy might not have been spontaneous and independent of the physical exercise. He had himself seen one or two less extensive cases of dystrophy in which the atrophy was recovered from without any treatment. In one of these cases the atrophy was limited to the muscles of the thumb in both hands.

DR. C. L. DANA said that he thought there was a class of cases of progressive muscular dystrophy brought on by excessive muscular work when the person was immature. This form of dystrophy seemed to him to have a different course from the ordinary types of dystrophies. He had seen cases in which he believed the lesion was in the muscles, and in which the course and clinical symptoms were those of dystrophies occurring in acrobats and gymnasts. In these cases the symptoms usually progressed steadily up to a certain point, and then there was an arrest of the process, and sometimes a very decided improvement. This clinical distinction should be borne in mind in estimating the value of the treatment pursued in this case. He doubted very much if such treatment would have much effect on the more usual form of atrophies. In the cases to which he had referred the upper arm, shoulder, and back were usually affected.

DR. B. SACHS said that the case seemed to him of great importance. He was perfectly familiar with the class of cases referred to by the last speaker—the localized atrophies and those due to excessive muscular exercise. The case under discussion, however, did not belong to this category. When first presented to the Society, two years ago, the involvement of the facial muscles was a prominent feature, and the improvement observed had been in the muscles other than the facial ones. There was, of course, room for doubt as to the

value of this particular treatment, yet it should be remembered that no improvement had been observed under other methods, and yet was prompt and decided under physical exercise systematically carried out. The original diagnosis of progressive muscular dystrophy was without doubt correct, and the result of treatment was certainly unique.

DR. JOSEPH COLLINS said that where the proton was diseased it should be evident that no amount of mechanical treatment would be of service, but if the form of progressive muscular atrophy were acquired, then treatment, including exercise, should be of some advantage. He thought, therefore, the case was very instructive. It was begging the question to infer that the improvement was independent of the treatment. He believed this to be a case of progressive muscular dystrophy of the acquired type, no evidence having been brought forward to show that it was heredity, and that the improvement was due to the treatment.

DR. G. M. HAMMOND said that the man had been an athlete and a runner, and yet had developed the muscular dystrophy; hence he could not understand why if the muscular atrophy had developed during exercise, it should be arrested and improved by a resumption of systematic exercises.

DR. C. HERTER said that the case was evidently one of the familiar form of progressive muscular dystrophy, and he felt that the systematic exercise must have had a beneficial effect in bringing about this change. One should not, however, draw too positive conclusions from one or two cases. The case was a most interesting example of what could be done by modifying favorably the nutrition of a part.

The PRESIDENT said that as far as the distribution of the dystrophy was concerned we certainly found cases in which it was exactly similar, and yet we could not trace the exact etiological factor. Where the hereditary element was not present it was possible that there was a better chance for improvement under treatment. He thought that we were warranted in trying systematic physical exercise, at least in cases in which the hereditary factor was not especially prominent.

Dr. JOSEPH COLLINS presented a pathological specimen of

TUMOR OF THE MEDULLA,

with the following history: S. J. J., aged twenty-eight years, denied syphilis, and had been extremely temperate. The first symptom, numbness in the fingers of the left hand, was observed eight months ago. This gradually spread up the arm, and later on a similar feeling was noticed in the left lower extremity. About five months ago he became so unsteady that he had to give up his work as a bricklayer, but continued working in a factory till two months ago. About three weeks ago he observed a "stiff feeling" in the left side of the head, and the left upper and lower extremities felt unwieldy. On November 22d, when first seen by the speaker, at the request of Dr. Kelly, the head was fixed and slightly drawn to the left. There was no real stiffness of the head, and no abnormality or tenderness. There was no ocular paralysis; the pupils responded to light and accommodation. The fundus was found quite normal. Vision and color-perception were normal. The senses of smell and taste were normal. There was no unsteadiness of articulation. The knee-jerks were both exaggerated, particularly on the left side, and there was left-side ankle-clonus. The triceps reflex was exaggerated on the left side. The left hand was decidedly ataxic. The patient could walk, and could move the upper extremity in every direction. There was a remarkable diminution of the pain-sense all over the body, including the mucous membranes. Tactile sensation appeared to be unimpaired. Temperature-sense was exquisitely preserved. The patient talked rationally, and the psychical sphere was intact. Examination of the urine showed albumin, but no sugar. The pulse was rapid, the respirations accelerated, and the temperture 102° F. The opinion was expressed that the intracranial lesion could not be satisfactorily localized, but that there was probably a new formation within the brain, subcortically involving the pyramidal projection on the right side. Three days later the patient was seen again, and was found much worse. He was quite somnolent, and the reflexes had become quite sluggish. There was already marked pulmonary œdema. An exploratory opening was made by Dr. J. E. Kelly, the surgeon in attendance, just behind the fissure of Rolando. A hollow needle introduced into the brain in various directions found no unusual collection of fluid. On the second day after the operation his temperature rose to 105° F., although there was no evidence of sepsis in the wound. He died December 1st. It was found on autopsy that a great part of the medulla had been destroyed by the tumor, leaving only a mere shell. The remarkable feature of the case was that the man appeared to be well in every respect up to a short time before his death, and yet nearly all of his medulla was gone.

REVIEWS.

STUDENTS' AID IN OPHTHALMOLOGY. By GERTRUDE A. WALKER, A.B., M.D. 40 illustrations and colored plate. Philadelphia: P. Blakiston, Son & Co., 1895.

WE think that the excellences of this little work—and they are not few—hardly justify its existence or counterbalance its deficiencies. It is too small and scrappy to serve as a hand-book or guide for any student desiring thoroughness, and its obligations to a very limited circle of teachers, coupled with a decided myopia or limitation of the field of vision as to others, is too evident. What can be said of a text-book that conveniently avoids the whole subject of the treatment of heterophoria with these words: "Various forms of nervous disturbance can be traced to faulty muscular power, and complete relief from headache and symptoms of eyestrain is often not obtained until appropriately placed prisms are combined with the lenses which correct the patient's focal error?"

SPECTACLES AND EYEGLASSES. By R. J. PHILLIPS, M.D. Second edition, revised. Philadelphia: P. Blakiston, Son & Co., 1895.

WE are glad to see that a second edition of Dr. Phillips' excellent little manual has been called for by the profession.

ORIGINAL ARTICLES.

THE NATURE AND TREATMENT OF MAMMARY NEOPLASMS.[1]

BY W. P. CARR, M.D.,
PROFESSOR OF PHYSIOLOGY, COLUMBIAN UNIVERSITY.

WE shall probably never arrive at anything like unanimity in our treatment of mammary neoplasms until we come to some definite understanding of their nature and morphological significance. And I believe that a too close following of microscopic appearances, and the attempt to classify each apparent variety as a distinct entity, have tended, and are tending, rather to lead us away from a true understanding of their real nature and consequent rational treatment.

We have divided tumors broadly into two classes, benign and malignant, and made many varieties or subdivisions of each class. Some of these varieties are generally conceded to be improperly named and classified; and there is much evidence, I may say even positive proof, to show that a given tumor may pass from one variety into another, or even from the one broad class of benign tumors to the other broad class of malignant growths.

I shall confine my remarks to some of the more common solid growths met with in the mammary gland, and endeavor to show the real similarity of structure in tumors that have been separately classified and that have at first sight markedly different anatomical characters. The most common tumor of the breast, the so-called adenoma, differs at first sight from the normal gland only in having a greater amount of connective tissue interposed between the glandular elements and in more or less irregularity in size and shape of these glandular elements.

But, as pointed out by Rannier, Virchow, and others, the vast majority of adenomata are really a growth of connective tissue into the tubular interspaces, and should properly be called fibrous, sarcomatous, or myxomatous tumors, in which the enclosed glandular elements are a secondary phenomenon.

Such a tumor is usually a true fibroma; but, if the infiltrating connective tissue be rapidly forming and rich in cells that have not had time to throw out fibrillary processes and become connective tissue, the growth would be properly classified as sarcoma. We cannot draw a sharp line between fibroma and sarcoma either clinically or with the microscope; nor can we always distinguish sarcoma from simple granulation-tissue the result of injury or inflammation. It seems clear, therefore, that the chief element of adenoma, adeno-sarcoma, adeno-fibroma, myxoma, and sarcoma is an infiltration of connective tissue more or less rich in cellular elements or mucilaginous material.

To go a step further, we may safely say that there are but two possible sources from which this infiltration of connective tissue may spring; and these are, first, the previously existing connective-tissue cells and, secondly, the leucocytes.

Two kinds of cells are found in connective tissue, the fixed cell and the wandering cell.

That fixed connective-tissue cells proliferate I very much doubt, but there is no reason to doubt the proliferation of the wandering cells, which are really leucocytes. However, be this as it may, we cannot question the fact that white blood-cells do, under a variety of circumstances, pass out of the bloodvessels and change into fixed connective-tissue cells. Nor can we doubt that much, if not all, of the new connective tissue formed at the site of various inflammations is derived from wandering leucocytes. The main function of some of the leucocytes seems to be that of changing into connective tissue for purposes of repair or for the walling up of some foreign body or deleterious substance. Granted then the infiltration of a tissue with leucocytes, we have the ancestor for our tumor. Let the fibrous mesh of the mammary gland become infiltrated with cells, as it invariably will under the influence of prolonged irritation; let these cells change into connective tissue, as they invariably will do under the same influence, and we have a tumor that will be fibrous or sarcomatous according to the slowness or rapidity of the process. We have only to find and *understand* the source of irritation to complete the etiology.

In order to make my propositions intelligible allow me to state some of the physiological processes known to occur in healthy tissues and in inflammations. We know that in the mammary gland we have a collection of gland-tubes surrounded and supported by a rather loose mesh of connective tissue richly supplied with bloodvessels and lymphatics. We know that normally there is a constant outpour-

[1] Read before the Medical Society of the District of Columbia, October 2, 1895.

ing of lymph or plasma from the vessels, and that this plasma flows between the meshes of the connective tissue, bathing and nourishing these cells and also those composing the gland-tubes, and finally finding its way into the lymphatics, to be returned to the bloodvessels. We know that the walls of the capillaries are provided with or can create small openings or stomata which allow white blood-cells to pass out in limited numbers and accompany the stream of plasma, while under ordinary circumstances the red corpuscles are unable to pass through these minute openings.

Let an irritant be applied, and the capillaries will become distended, plasma and cells pass out much more rapidly than in health, and the loose connective tissue becomes packed with cells and plasma. Stop the irritation, and the capillaries return to their normal condition, the infiltrating cells and plasma are carried off by the lymphatics, and the part returns to its normal condition. But let the irritation be continued long enough, and the infiltrating cells begin to change into connective tissue. They will continue to come out of the bloodvessels and form connective tissue as long as the irritation is continued. After a time indeed this newly formed tissue may act as a foreign body and become encapsulated. Whether or not the tumor will continue to grow depends perhaps upon several conditions, such as the continuation of the irritation, the resistance of the tissues, the completeness of the nervous control of the fixed cells of the tissue, and the amount of nutrition supplied. That fibrous and sarcomatous tumors have frequently originated at the seat of an injury cannot be denied, *nor can it be proven that most tumors have not been preceded by some inflammatory infiltration.*

There is much evidence to show that benign as well as malignant tumors usually occur in some tissue that has been the seat of such infiltration. I have myself seen four cases of what appeared to be a simple mammary abscess develop into a tumor. In one case into a carcinoma, in one into a rapidly fatal small round-celled sarcoma, and in two cases into fibromata or so-called adenomata that continued to grow and developed into large tumors. In fact, all inflammations that result in destruction of tissue or suppuration leave behind them a certain amount of fibrous infiltration enclosing gland-tubules that would present exactly the microscopic appearance of adeno-fibroma. I have in my possession a section showing this condition, taken from the breast of a woman who died of chronic parenchymatous nephritis soon after the healing of a mammary abscess. It cannot be distinguished from ordinary adenoma.

Keloid growths in scars are common. The frequency of occurrence of tumors in any organ is in proportion to the amount of exposure of that organ to inflammatory influences. Seventy per cent. of all tumors in women attack the reproductive organs, and it is safe to say that seventy per cent. of all prolonged inflammations are similarly situated. The mammary gland is peculiarly exposed to traumatic injuries, to bacterial invasions, and to prolonged and chronic irritation of a reflex character from the uterus. Its loose anatomical structure seems particularly favorable for tumor development and growth.

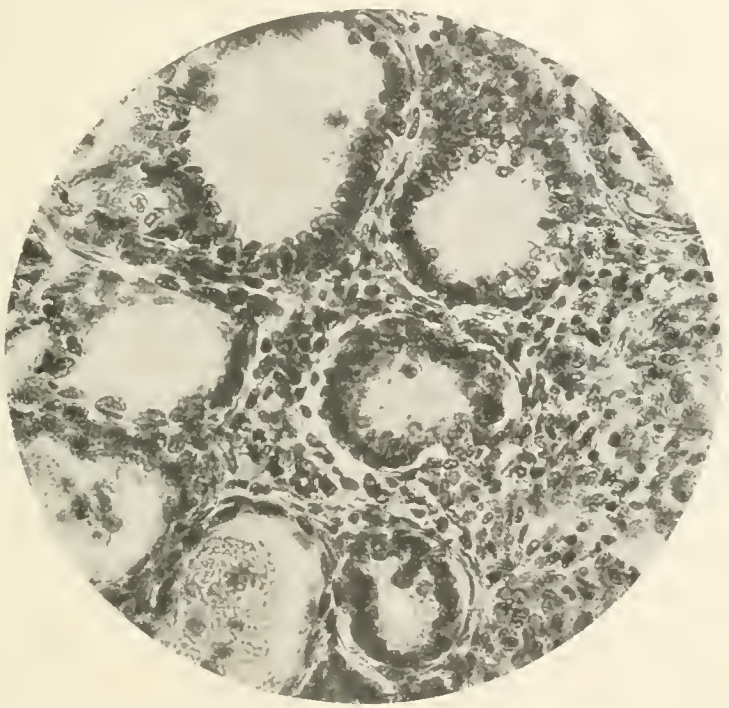
I am aware that these views are diametrically opposed to some recent and high authorities. Mr. Roger Williams, F.R.C.S., has recently published a monograph upon diseases of the breast, of which J. William White[1] says: "Mr. Williams, whose previous work in this same direction has been noteworthy, has now given to diseases of the breast a broad and comprehensive consideration which makes his monograph the most valuable contribution of recent years to our knowledge of the subject." Mr. Williams' book is undoubtedly of great interest, for he has carefully collected and arranged a vast array of facts bearing upon his subject. He makes, however, the startling statement that 95.74 per cent. of all breast-tumors are of archiblastic origin, and only 4.26 per cent. of parablastic origin. If we really believed that nearly 96 per cent. of all tumors of the breast were of epithelial origin, there would be no excuse for leaving any tumor in a breast a moment longer than necessary for its removal; but the explanation of this statement by Mr. Williams is that he regards the common adenoma as an archiblastic tumor because he finds in it the epithelial lining of the glandular ducts, which he believes to be originally derived from the ectoderm. This is, in my own opinion, so grave an error as to destroy the foundation of all his subsequent deductions. Again, says J. William White: "He minimizes the influence of trauma and of pre-existing inflammatory lesions, contrary to the widespread belief both in the profession and among the laity, and concludes his careful review of this part of the subject as follows: 'The outcome of all this is that intrinsic causes are much more important factors in the origination of cancer than extrinsic ones, which are by no means its necessary antecedents. In the vast majority of cases the outbreak of this disease seems to be entirely spontaneous; that is to say, it cannot be attributed to the immediate action of any appreciable extrinsic cause whatever. The occasional transformation of innocent into malignant growths must be admitted.'" But he thinks this is very different from admitting that such neoplasms are specially prone to develop into malignant disease.

Here again his reasoning, I think, is faulty. He persists, like many others, in refusing to take into consideration the statement invariably made by

[1] American Journal of Medical Sciences, October, 1894.

cancer-patients that the cancer was preceded by some traumatic or inflammatory condition, while he accepts without question any other statement that the patient may make. I began my medical career with the same prejudice. I did not believe that cancers or benign tumors were usually preceded by inflammatory changes. I was annoyed by the persistence with which patient after patient gave the history of a bruise or an abscess, then a knot or lump; then, perhaps, a period of quiescence, then a rapidly developing tumor.

A case came under my observation of a bruise followed by an abscess. The abscess was evacuated and a brawny infiltration remained. In a year the brawny infiltration had disappeared, but a mass of



connective tissue could be felt deep in the gland at the seat of abscess. A year later this tumor began to grow rapidly and became painful. In order to remove it I found it necessary to remove the whole breast, and I was much surprised to find the tumor a typical adeno-fibroma, with a typical nodule of scirrhous carcinoma in its centre. This case I reported in full in the *Virginia Medical Monthly* for December, 1891. There is no anatomical bar to such an occurrence. It is contraindicated by no known physiologic or pathologic law. On the contrary, it is just what we would expect to occur under the circumstances: at least, up to the point of formation of the fibrous tumor. Then why should we throw out the overwhelming mass of testimony to show that tumors, both benign and malignant, are usually preceded by inflammatory conditions?

Let us go a step further and see how a benign tumor may become malignant. It is acknowledged by nearly all authorities that this change does occasionally take place. Mr. Williams admits it, while he deprecates its importance and minimizes its frequency. We can readily understand how a fibrous growth may become sarcomatous when we remember that there is no sharp anatomical distinction between these two classes. An increase of irritation, a more rapid cellular infiltration, is all that is necessary to make the change.

With carcinoma the case is somewhat different. We must introduce a new element—the proliferating epithelial cell. In every fibrous tumor of the breast we have epithelial cells lining the glandular ducts.

Physiology teaches us that these epithelial cells are under the influence of nerves, presumably by contact with a minute axis-cylinder fibril. Golgi's method of staining has shown us that these minute nervous fibrillæ exist in great numbers where they were previously unsuspected, and that they come into close proximity, if not actual contact, with each cell. There is scarcely a doubt that we shall now be able to trace them to the epithelia contained in adenomata; but it is easy to conceive that the contraction of newly formed connective tissue or that inflammatory infiltration may destroy by pressure all such nervous connection with some of the glandular epithelial cells. We would have then a cell resembling an amœba entirely severed from all connection with the central nervous system, free to revert to its ancestral type, free to multiply *ad libitum*, free to wander into new fields and infil-

trate new tissue, provided the ever-active leucocytes allow it to do so. Such a cell may prove to be the long-sought cancer-bacillus or cancer-amœba. As in the case of bacterial invasions, a warfare would immediately begin between the invaders and the leucocytes, and the result would depend upon the relative numbers and activities of the opposing forces. Let the leucocytes succeed in surrounding and closely walling up the invaders, and they may be held prisoners indefinitely or die and degenerate in their prison. In this way some of the cysts and cheesy nodules found in older mammary adenomata may originate. In such cases the tumor would remain temporarily benign, but would increase in size.

In some cases the invaders may be few and scattered, and may be squeezed out of existence by the connective-tissue development without leaving behind a tangible trace. We may thus account for the source of continued irritation and growth in some apparently benign growths. Indeed, the possibilities are almost unlimited. Once get a few epithelial cells separated by inflammatory infiltration, or connective-tissue development, from the general nervous system, and the varying fortunes of war between them and the leucocytes, influenced as they are by the relative activities and numbers of cells on either side, by the vascular supply and consequent reinforcement of leucocytes, by the vigor and resistance of the fixed cells of the tissue, and by many other remote and direct conditions, give us data sufficient to account for all the phenomena observed in tumors of the breast. It would take up too much time and be out of place here to attempt to show all the many ways in which the scale may be turned in favor of one or the other of the opposing armies; but we can readily understand how, if the invading archiblasts increase and travel a little too fast for the leucocytes to surround and imprison them, we will have exactly the conditions necessary for the formation of scirrhus: acini here and there, filled with cells, and a continual escape of a few scattering invaders into surrounding tissue, there to repeat the process or to be taken up by lymphatics and carried to distant parts, to start a new focus of infection. On the other hand, if the leucocytes are of sufficient activity, they will succeed in either destroying the invaders or holding them in check, and the growth will appear benign, or may even remain stationary for long periods; but if such a condition of affairs exists, there will always be danger of an irruption.

The evidence in favor of such a theory is considerable. In the first place, there is in it no contradiction of any known anatomic condition or physiologic law. On the contrary, it is just what we would expect under the circumstances from our knowledge of biologic processes in general. It coincides with and explains all known facts, and makes intelligible many facts that are otherwise mysterious or inexplicable. Each step in the process is known and admitted actually to occur in nature under similar circumstances. Microscopic sections apparently show these processes actually taking place. The accompanying microphotograph of an adeno-sarcoma, kindly given me by Dr. Gray, of the Army Medical Museum, seems to show an eruption of epithelial cells from a broken-down tubule that is surrounded by a mass of fibrous tissue and apparently deprived of nerve-influence.

Patients with malignant tumors almost invariably give a history of previous inflammatory affections, although this evidence has been persistently and systematically ignored. Malignant tumors are more frequent in organs most subject to inflammatory and traumatic irritation. Indeed, it would seem that they never occur in normal healthy tissue, but always in some previously infiltrated tissue.

In view of these facts, it seems more than probable to me that malignant growths usually originate in some previous inflammatory condition or fibrous tumor. However this may be, when we come to deal practically with mammary neoplasms we must admit that in their incipiency it is impossible to say whether they are malignant or benign, and that, even when well developed, apparently benign tumors sometimes suddenly take on the characters of malignancy. We must also agree that it is only in the very early stages of carcinoma that we can expect a large percentage of cures from removal of the growth; but, of course, all inflammations do not necessarily produce tumors of any kind. To produce a malignant tumor we must have prolonged irritation, and finally a separation of some epithelia from central nervous influence, and not only so, but we need perhaps a certain amount of inactivity or debility of leucocytes. This may be hereditary and account for the hereditary tendencies to cancer, or may be acquired in a variety of ways. The majority of surgeons to-day agree with Heidenhain that carcinoma is at first a local disease, and that recurrences are due to incomplete ablation. I wish to emphasize the fact that it is only very early in its development that we can make a complete removal. The very moment that the usual signs of malignancy begin to show the chances for complete removal become greatly lessened. The fact that some cures result from late operations does not in any way invalidate this statement. It is the general belief, borne out by the experience of others and by my own, that operations properly done at a sufficiently early period will almost invariably prove successful. In 1890 and 1891, and the early part of 1892, I operated upon four cases at a very early period, before there was any fixation, enlargement of glands, or other

sign of malignancy. In fact, in each of these cases I supposed the tumors to be benign before beginning the operation; but the lack of encapsulation and some infiltrating streaks of connective tissue led me to remove the entire gland. The axilla was not opened. Microscopic examination of these four tumors showed them all to be carcinomas. One of these patients, above referred to, was nineteen years old at the time of operation; the others were aged respectively twenty-eight, thirty-one, and thirty-eight. All are still living under observation, and after more than three years have had no recurrence. Since 1892 I have operated in a similar manner upon five others at an early stage; all proved to be carcinoma by microscopic examination, and are free as yet from recurrence after a period of from two and a half years to two months. Sufficient time, of course, has not elapsed to say that the latter five cases are cured; but I feel quite sure that there will be no return in any of them, and that a complete removal of the gland while the tumor still has the clinical appearance of a benign growth will give us nearly 100 per cent. of cures. Contrast this with the statement made by the elder Gross, shortly before his death, to the effect that he thought he had never cured a cancer, but operated merely for moral effect. If anything like 100 or even 50 or even 25 per cent. of cures is to be obtained by any operation, that operation must be done very early—so early in fact that we will not be able to say that the growth is malignant until we have made a section of it. The longer we wait the smaller will be the percentage of cures. Are we then justified in removing every tumor of the breast as soon as discovered? I think we are, for the following reasons:

Cancer is increasing more than any other known disease. Williams, in his recent work on *Tumors of the Breast*, estimates the number of cancers in England and Wales in 1840 at 4500, and in 1895 at 40,000. No other disease can show anything like such an increase. I have recently seen statements from reliable sources to show that the increase in America is in about the same ratio. In the case of any given incipient tumor of the breast in a woman between thirty and forty years of age, the chances are that it is malignant. Earlier or later in life the chances become more and more in favor of the tumor being benign; but I hardly think we should dare to await development, even if the chances were ten to one that it would prove benign. After a tumor has attained a considerable growth and remained for some months without perceptible change and without showing evidence of malignancy, the chances that it will ever do so are comparatively small. Every time this subject is mentioned some one will arise in the discussion and say: "Why, I know a woman, Mrs. So and So, who has had a tumor of the breast for thirty years, and another who carried one for twenty-five years, and you need not tell me these tumors should be removed." Now, I grant that such tumors do usually run a benign course to the end; but I think if you will be on the lookout for such cases, as I have been for two or three years, you will soon be surprised to find how many of them suddenly give evidence of malignancy. They have either been malignant from the first, or some battle has been going on in them all these years, such as I have described above. I can give no figures as to the frequency of such a change. It is impossible at present; but my own idea is that at least one out of ten apparently benign tumors will undergo a malignant change sooner or later if not removed. And this change may possibly take place after removal, as instanced by a case related to me by Dr. Gray, of the Army Medical Museum. He examined a tumor that had been removed and found it benign; but a recurrence took place, and the second growth was malignant. If there is any truth in the foregoing observations, the chance that any given tumor of the breast is malignant or will become malignant is anywhere from 10 to 50 per cent. With such a prospect or even with chances of one in a hundred for malignancy, I think we should not hesitate to operate. Even leaving out the question of malignancy altogether, it seems to me there are sufficient reason and justification for removing all tumors of the breast at an early period.

They are always a source of anxiety and annoyance. They are often painful at times, particularly at the menstrual periods, and they usually continue growing for a long time and become more and more troublesome as time passes. There is scarcely any danger in the operation. Almost the only objection is on cosmetic grounds, and it is questionable in my opinion whether a tumor is more a thing of beauty than a scar; but if the operation is done at a sufficiently early period, there need be little disfigurement unless the growth presents some evidence of malignancy. If the tumor is encapsulated, I think it is sufficient to remove it entire in its capsule. And if the tumor is small, there will be very slight disfigurement; but if the tumor is not encapsulated, the whole gland should be carefully removed. I do not believe it is necessary or advisable to open the axilla unless there is at least a suspicion of malignancy.

I have said nothing about microscopic examination before operation, because I believe cutting the tumor before operating for its removal may cause a rapid change or an escape of cells that will infiltrate new tissues and perhaps be the cause of recurrence. And there is no doubt in my mind that all these tumors should be removed without any cutting into the tumor, without rough handling, pulling, or

squeezing. All cases should be examined microscopically after removal and recorded for future statistics. I imagine that many surgeons would be greatly surprised if they could see sections from all the small tumors they have thrown away without examination. There would be a vastly greater per cent. of malignant growths among them than most of us suppose. I would also urge that these microscopic examinations be made with great care by a competent man, and that he be given the whole tumor to examine, for it often happens that tumors present very different appearances in different parts of the growth.

There is little or no difference of opinion as to what should be done for plainly malignant growths. Thorough removal is the only hope, and the present operation of removing the pectoral muscles and axillary fat and glands is perhaps the best that we can do; but there are two very distinctly different ways of performing this operation. I shall briefly describe what I believe to be the important points to be observed. Begin with the axilla, so as not to force any cancerous material or cells from the axilla into the deeper tissues while manipulating the breast. Cut down to the axillary vessels, and tie all branches passing into the tissue to be removed. Remove the axillary contents in one mass by clean cutting with a sharp knife and without picking or pulling. In this way the axilla can be thoroughly cleaned in one-tenth the time and with less danger and hemorrhage, and less danger of squeezing infecting cells into the tissues that are left. Extend the incisions down over the tumor so as to enclose and remove all diseased skin and a considerable margin, at least an inch, of healthy skin. Turn back the healthy skin on each side so as to expose all tissue to be removed, and then remove it in one piece by clean cutting.

I would like also to say a word against any operation after a well-marked cancerous cachexia has appeared or secondary growths have begun in internal organs, unless it be clearly understood by all concerned that it is only for palliative purposes. The undertaking of hopeless operations, as a rule, only brings surgery into discredit, and deters others from undergoing proper operations at the proper time. Patients with tumors have inquiring dispositions and communicative friends. They hear of every failure in the city, and are often in this way persuaded to put off an operation until forced to it by suffering, when it is too late.

THE school census which was ordered to be taken by the police department in New York City has been completed in all but eighteen districts. The reports so far received show that 399,314 children have been enumerated.

CURETTAGE IN THE TREATMENT OF TRACHOMA.

BY A. N. STROUSE, M.D.,

OPHTHALMOLOGIST TO MT. SINAI HOSPITAL DISPENSARY; CONSULTING OPHTHALMOLOGIST TO BETH ISRAEL HOSPITAL; OCULIST AND AURIST TO ORPHAN ASYLUM OF ST. VINCENT DE PAUL.

IN view of the frequency and obstinacy of this affection, a large number of methods of treatment have been suggested from time to time, many of which, after a brief period of trial, have been relegated to obscurity. It is my intention here to discuss briefly those procedures which are most extensively employed at the present time, and then to describe a method which in my hands has proved superior to all others, and has practically taken their place in my practice. My remarks apply chiefly to the severer forms of trachoma, although it must be remembered that even in the milder varieties recourse must now and then be had to radical measures.

Probably the method which still enjoys the widest popularity among ophthalmologists is the application of such caustics as the solid stick of sulphate of copper or pure alum. This serves a useful purpose in milder or more recent cases, but after it has been given a fair trial it is often found that, after a certain amount of apparent improvement has been effected, the disease remains stationary, and in that event more radical measures are demanded. At any rate, even in favorable cases, the treatment by caustics is usually protracted, and requires a considerable degree of perseverance on the part of the physician and his patient, while it is often quite painful, especially at the commencement.

Among the operative procedures the one most in vogue is expression. The cruder way of practising this procedure consists in squeezing out the contents of the follicles by means of the finger-nail, or the copper stick when applying it. This, however, is less thorough and effective than the use of one of the various forms of forceps devised for this purpose, among which the roller-forceps of Prof. Knapp is the most applicable. Expression has certain disadvantages which, in my opinion, greatly detract from its value, chief among which are the following: The forcible expulsion of the trachoma-follicles produces extensive laceration of the delicate conjunctival tissues. The deeper-seated follicles are evacuated with difficulty. The pressure required to eradicate the disease thoroughly, especially if, as frequently happens, the roller of the instrument does not rotate, but glides over the surface, is so considerable that the underlying tissues are subjected to severe contusion, which retards healing of the affected part. In consequence of this the reproduction of normal epithelium, after expression, is impaired, and an excessive amount of cicatricial tissue produced; moreover, certain parts of the con-

junctival sac cannot readily be reached with the roller-forceps. Aside from these objectionable features, the pain attending this method is so marked as to necessitate the employment of general anæsthesia.

Among operative procedures in the treatment of trachoma, grattage, next to expression, is probably most often resorted to at the present day. As commonly practised, this operation consists essentially of scarification of the conjunctiva with an instrument provided with a number of sharp blades, followed by rubbing with a stiff brush moistened with a strong solution of bichloride of mercury (usually of the strength of 1 : 500). The brushings are repeated once daily for a week, at the end of which time a cure is sometimes effected. An extensive trial of this method has led the majority of ophthalmic surgeons to discard its use, as it has been demonstrated that its disadvantages more than counterbalance whatever benefits may be derived from it. Extensive cicatrization is apt to result in consequence of the numerous and necessarily deep incisions, producing contraction of the conjunctiva of the lid, and entropion. Very little of the normal conjunctival membrane is visible after the operation, its place being taken by a cicatricial mass. Equally common sequelæ are cicatricial bands between opposing surfaces of the ocular and palpebral conjunctiva. This method, like expression, requires general anæsthesia, as it is attended with so much pain that the local application of cocaine is unavailable.

Excision of the retrotarsal fold may be dismissed with a few words, as it is an incomplete and unsatisfactory method, and is but rarely employed. The same objections apply to puncture of the trachoma-follicles with the galvanocautery-point, as well as to abscission and evacuation of the follicles with the needle, and similar procedures.

Recognizing the uncertain results derived from the methods above described, I was led about five years ago to devise a plan of procedure which in my hands has proved its superiority over all others with which I am acquainted.

This method consists essentially in curettage of the trachomatous tissue with a sharp curette shaped like a cataract-spoon. The cutting-edge of the instrument measures about 1.5 mm. in width, and is ground sharp in its entire circumference, while the back of the curette is flat and smooth.[1] The shank should be elastic and yet sufficiently firm to withstand ordinary pressure, and is attached to a metal handle, so that the instrument can be properly sterilized. (See illustration.)

[1] It was suggested to me that the spoon be fenestrated, but this is not advisable, for if the back of the instrument should come in contact with the cornea it would undoubtedly do more or less damage. The curette is made for me by F. G. Schmidt, N. Y.

After thoroughly cocainizing the conjunctiva the lower lid is everted and rapidly scraped over its entire extent. Then the upper lid is everted and held between the thumb and finger of one hand, while the curette is passed up into the fornix, and this part of the conjunctival sac scraped, care being taken to penetrate all the folds. The everted portion of the lid is treated last. During the entire procedure, which occupies but a few minutes, an assistant mops the lids with absorbent cotton dipped in an antiseptic solution (a saturated solution of boric acid or a bichloride solution 1 : 10,000).

When the hemorrhage, which is only slight, has ceased, we see a surface which is smooth except for a number of depressions or small cavities. These are deep or shallow, according to the seat of the trachoma-bodies contained therein. The surfaces are now thoroughly washed and touched with a 2 per cent. solution of nitrate of silver. This is really the only part of the operation that elicits any pain, and by the instillation of a few additional drops of cocaine even this may be entirely avoided.

The after-treatment consists in the application of iced pads for one-half to one hour, and by the end of this time any reaction will be found to have subsided. That the reaction, however, is inconsiderable is shown by the fact that ignorant dispensary patients, who frequently neglect to obey instructions, rarely complain of any inconvenience following the operation. The patients are ordered to return every other day, when they are again treated with the silver solution. The latter has given me better results than the 1 : 500 bichloride solution, which I first employed when it was recommended by the advocates of grattage. After the eighth to tenth day, when the epithelium is completely regenerated, and the cavities left by the trachoma-follicles have completely granulated and are flush with the surface of the conjunctiva, I sometimes discontinue the silver application and resort to the copper stick. This treatment is continued for the following week or two, at which time the patients are usually completely cured. The palpebral conjunctiva is now smooth, the thickening and induration of the lids have markedly subsided, and pannus, if it has existed, shows a tendency to subside without further treatment, or even may have disappeared completely.

If at the end of four weeks the cure is not complete, the curetting should be repeated. The second operation is even of a more simple character than the first, as it is not necessary to curette so deeply and extensively, and naturally the reaction is even slighter than before.

This, in brief, is the plan of treatment which, in my opinion, should be given a high place in the therapeutics of trachoma. I will not occupy your time by reports of cases nor weary you with an extensive bibliography of the subject. As far as I am aware, Sattler was the first to call attention to the value of curettage in the treatment of trachoma; but for some time previous to the publication of his article I had been employing the operation devised by me and demonstrating its technique to my class of students at the New York Polyclinic. The method differs essentially from that of Sattler, who resorts to puncture of the follicles with a cataract-needle before the use of the curette. Davier, who has employed Sattler's method, lays less stress on the scraping than on the brushing and washing of the cul-de-sac with sublimate solution. Secondi recommends curettage followed by expression of the follicles with a special forceps. Peters advocates scraping the mucous membrane with a dull lancet. In fact, as far as I can learn, all those who have employed curettage have combined this procedure with scarifications, brushing, needling, expression, and other auxiliary measures, and no one has made use of curettage, pure and simple, as recommended in this article. It might be supposed that the removal of the conjunctival epithelium and deeper tissues with the sharp curette would be followed by extensive formation of cicatricial tissue; as a matter of practical experience this is not the case, the epithelium is almost completely regenerated, and the subconjunctival tissues assume a soft and pliable character except where scars had resulted from deeper-seated trachoma-follicles.

Indeed, this seems perfectly explicable when it is remembered that the curettage of granulation-tissue, and necessarily of more or less of the deeper structures, is constantly resorted to in other mucous surfaces of the body, with the result of a perfect restoration of the function of the affected membrane.

In conclusion, I would emphasize the following advantages which curettage possesses over other methods advocated for the treatment of trachoma:

1. Its uncomplicated technique and the rapidity with which it can be performed.

2. Its comparative freedom from pain, enabling us to dispense with general anæsthesia.

3. The minimum injury inflicted upon the conjunctival and subjacent tissues.

4. The absence of inflammatory reaction after operation, permitting the patient to follow his usual occupation without discomfort. This is an important point in its favor in comparison to other operative procedures which confine the patient to his room for several days.

5. The simplicity of after-treatment, which is of importance, in view of the fact that the majority of trachoma cases occur in the lower walks of life.

6. The radical character of the operation, recurrences being rarely observed.

TETANY, WITH ILLUSTRATIVE CASE.

By GEORGE W. MILES, A.M., M.D.,
of Oneida, N. Y.

Very little mention of the disease known as "Tetany" is found either in text-books of general medicine or in special works on nervous diseases. An interesting and exhaustive study of the subject has been published by Professor J. P. Crozer Griffith, of Philadelphia.[1] Dr. Griffith expresses surprise at the scarcity of records of tetany to be found in American medical literature, and speaks of the disease as one of "rare occurrence in this country."

A short time previous to the publication of Dr. Griffith's paper (December 11, 1894) I reported to the Madison County (N. Y.) Medical Society a case of tetany occurring in my practice. It is possible that, in view of the conceded infrequency of the disease, a brief consideration of the subject of tetany, in connection with the history of my own case, may be of interest.

In a work published quite recently is found the following definition of "Tetany," "Tetanilla," or "Little Teta-nus": "A functional disease of the nervo-muscular apparatus, characterized by the occurrence of paroxysmal tonic spasms that involve certain groups of muscles, and that in severe cases may extend to nearly all the voluntary muscles of the limbs and body." This definition gives little idea of the terrible intensity of suffering that marks the clinical history of tetany. The nerves that are concerned in the production of the contractions exhibit an immense increase of electrical and mechanical excitability. The functional character of the disease has led many observers to doubt the propriety of dividing it from other functional spasmodic disorders, or as to regarding the disease as a separate entity. The disease is observed more frequently by physicians in general practice than by those whose experience is limited to office and consultation practice. The weight of opinion seems to be that tetany occurs most frequently among children. The influence of sex is not very decided. Persons who have been exposed to cold or wet seem to be particularly liable to attacks of tetany. Stubborn constipation or any intestinal irritation is liable to provoke an attack. Dentition is said to be, likewise, a cause. Attacks occur also in connection with other diseases, particularly typhoid fever. Constitutional causes favor its development.

[1] American Journal of the Medical Sciences, February, 1895.

When a predisposition to tetany exists almost any irritation of the cutaneous or mucous surfaces may excite an attack of the disease.

The occurrence of an attack is usually preceded by certain premonitory symptoms, as dizziness, determination of blood to the head, humming noises in the ears, and disturbance of vision. When the attack is matured, the force of the paroxysms is expended upon certain groups of muscles, the flexors being affected more frequently than the extensors. Neuralgic pains and soreness are complained of, headache, dizziness, and other cerebral symptoms of sensory disorder. The increased and inordinate excitability of the motor nerves is further indicated by their behavior under the influence of mechanical stimulation, a slight tap upon the nerve-trunk being sufficient to arouse a paroxysm. The duration of a paroxysm may vary from a few minutes to many hours, or even two or three days. The disease might be confounded with tetanus, but is lacking in the rapidly increasing severity of the phenomena of that terrible disease. Although a few examinations post mortem have been made in tetany there is little known of the pathology of the disease. One observer claims to have found a periarteritis and a periphlebitis of the bloodvessels of the white commissure and of the anterior horns of the cervical portions of the spinal cord. Others have found nothing of the kind, but, in the place of pathological facts, have built up an ingenious theory that the attacks of tetany are due to an irritable condition of the gray matter of the medulla and spinal cord, and that this irritable condition is due to sympathetic disturbances, causing irregularities in the vascular innervation of the bloodvessels of the spinal cord. This, however, does not appear to be a very lucid explanation of the attacks. The disease is seldom fatal, but sometimes persists for a considerable period of time. In these lingering cases a certain degree of muscular contracture and weakness is often evident after the cessation of spasmodic attacks. The disease has a distinct symptomatology, and this will be best illustrated by the narration of the case before mentioned.

In October, 1894, Florence S., a girl, aged seven years, was brought to me with the request that she be vaccinated. I performed the minor operation in the ordinary way, and in the usual site upon the left arm. About ten days later severe inflammatory symptoms supervened upon the full development of the pock, caused by undue traumatism, the child having injured the arm and destroyed the original vesicle by scratching or rubbing it during sleep. The inflammation was readily relieved by an anodyne and astringent lotion. A considerable wound resulted, however, and there was sloughing of the skin over a space as large as a silver half-dollar. After subsidence of the inflammatory action the healing process was rapid and the arm improved daily. About six weeks after the vaccination, on the morning of November 14th, I was asked to see the child, the parents being much alarmed about her. At this time the sloughing surface upon the arm was rather an insignificant one. The general symptoms, however, were severe and so closely simulated tetanus as to be startling, to say the least. There were tonic spasms of the arms and legs, succeeded by the same condition in the muscles of the neck and back, and likewise in the abdominal muscles. In the latter, particularly, the rigidity was so great as to elicit cries of pain. The muscles of the neck remained for the most part in a state of tonic contraction, so that any movement of the head was rendered quite impossible. The rigidity of any of the muscles was so great that passive movements were impossible. The muscular groups of the forearm, the upper arm, and the legs were involved. The facial muscles were affected, and the grimaces and contortions resulting served more thoroughly to alarm the friends. The muscular spasms were bilateral. The tips of the fingers and thumbs were drawn together into a conical shape. Some of the toes were flexed and bent laterally under the other toes. The upper arms were drawn against the sides of the thorax and the forearm strongly flexed. There did not seem to be any involvement of the muscles of the diaphragm or bladder, as reported in some cases. These paroxysms lasted only a few moments at a time, but continued intermittently for three or four days, and in the beginning at least the phenomena of tetanus were closely counterfeited. Opisthotonos occurred frequently during the first day. Several authorities, while speaking of the startling resemblance which tetany bears to genuine tetanus, mention as distinguishing the diagnosis that trismus occurs in the outset in tetanus, and is not apt to be or is not often found in tetany. In this case this diagnostic aid was not given me, as the initial spasm of the masseters was a prominent feature of the case. The jaws were so firmly set together that the handle of a spoon could not be inserted flatwise. Any attempt to stir the child in bed was immediately followed by a tense and extremely rigid condition of the entire muscular system. The increased mechanical excitability, which is a well-marked symptom of tetany, was very prominent in this case. The slightest sound, even speaking the patient's name or extending the hand toward her or touching the surface was sufficient to produce a paroxysm. These spasms continued, as I have said, for three or four days at irregular intervals. The patient slept very little for all of that time during the day or night, a light sleep of fifteen or twenty minutes being followed by her awakening with screams and new paroxysms and pain in the contracted muscles. The pain complained of was sometimes in the jaws, sometimes in the left arm, sometimes in the abdominal muscles. Following each spasm the entire surface of the body was bathed in perspiration. While in the beginning the spasms occurred several times in the space of an hour, the intervals of relaxation became gradually lengthened, and much

relief was obtained, though some stiffness of the muscles remained after three or four weeks. After the second day the relaxation of the jaws for a portion of the time was sufficient so that a tube could be inserted between the teeth, and in this manner it was necessary to introduce nourishment. This method of feeding was followed for about two weeks, as for that entire period the masseter muscles were never entirely relaxed except occasionally during sleep. The bowels were greatly constipated. The pulse during the height of the attack remained at about 140 at night and 120 in the morning. There was very little rise in temperature, at least not to exceed a degree. I learned that for a couple of weeks preceding the complete attack nervous symptoms had been noticed by the parents, slight rigidity of the muscles, disturbances of vision, etc. The result of this case was complete recovery. Convalescence was considerably prolonged.

While the condition in this case at first sight was, as I have said, quite startling, and the simulation of true tetanus was great, still the complete recovery (a circumstance not within my experience in tetanus), a consideration of the latent period which had existed, the prominence of the mechanical excitability, the complete relaxation of all the muscles during the intervals of the attack, all of this leads me to the belief that the disease was not the graver one. The idea of an hysterical element in the case was not lost sight of, but all symptoms and the entire history seem to admit of classifying this case with those of tetany already reported.

How much, if anything, the vaccination or the wound following had to do with the symptoms which existed I do not know. I imagine that these matters were neither directly nor entirely causative. In the minds of the frightened parents, however, the vaccination was the only thing prominent, and the night-calls, the extra work, and the unnecessary trouble that was made me for three or four days were such as almost to make me wish that the immortal Jenner had never been born.

I know that the child is of a general neurotic temperament; she was of a constipated habit; she had been exposed to the cold and wet; she had at the time an extremely sore mouth, the result of digestive disturbances. Each of these things and many others are believed to have been causes of special cases of tetany. I have no doubt that some or all of them entered into the etiology of this case, and it is possible that the irritation of the cutaneous surface by vaccination may have likewise been a factor.

THE CHAUTAUQUA COUNTY MEDICAL SOCIETY will hold its semi-annual meeting at the Sherman House, Jamestown, N. Y., on January 14, 1896. An attractive programme has been arranged, and a cordial invitation of attendance is extended to the profession of Chautauqua and adjacent counties.

IMPERATIVE CONCEPTIONS AS A SYMPTOM OF NEURASTHENIA.[1]

BY THEODORE DILLER, M.D.,

PHYSICIAN TO NEUROLOGICAL DEPARTMENT OF PITTSBURG FREE DISPENSARY; VISITING PHYSICIAN TO ST. FRANCIS' HOSPITAL, PITTSBURG.

UNDER the term imperative conceptions have been described a great variety of morbid impulses and fears which thrust themselves into consciousness. They may arise in a great variety of mental states or be present as an isolated symptom. They are always to be regarded as a symptom, never as a disease. The term imperative conception is somewhat misleading in that the command it implies is by no means always obeyed. Morbid impulses may frequently and for many years arise in an individual, and yet always be successfully resisted.

Probably in all of us impulses, fears, or doubts arise suddenly in consciousness as isolated thoughts or emotions, and which may be apparently totally disconnected with the mental state immediately preceding their appearance. For instance, many of us, I presume, have been seized with the desire to count the windows or doors in passing along a street, or in walking to avoid carefully the cracks in a pavement or to touch fence-posts. Looking from a great height the idea occurs to most persons to precipitate themselves below. The sight of a fragile piece of china or glassware suggests the idea that it could be readily crushed. A helpless child or a feeble invalid suggests how easily each could be killed. Certain words or phrases, lines of poetry or bars of music, may thrust themselves into consciousness at odd times.

These simpler forms of imperative conceptions cannot, of course, be considered abnormal in view of the fact that they probably occur in some shape to all persons. In normal individuals they never result in action contrary to volition. In their exaggerated form, whether seen alone or in conjunction with some neurosis or psychosis, they constitute a serious symptom, and may be the dominant feature of a grave form of insanity. Between the extremes there are all gradations; and to say when an imperative conception ceases to be physiological or within the bounds of health would be as difficult as to say where sanity ends and insanity begins.

Many morbid impulses and fears have received special names. The impulse to steal has been called kleptomania; to set fire to property, pyromania; the fear of open places, agoraphobia; the fear of narrow places, claustrophobia; the fear of dirt, mysophobia; the fear of crowds, anthropophobia; fear of fears, phobophobia.

The French, especially Morel, have described

---

[1] Paper read before the Pittsburg Academy of Medicine, December 23, 1895.

and isolated two forms of obsessions, which have been named *délire du toucher* and *folie du doute*. Fear of contamination and doubts are, of course, present within the limits of health. Many individuals are hypercritical as to cleanliness, or unduly fear disease, or contagion. Doubts arise in all of us. The uncertainty as to whether a letter posted was sealed or had a stamp affixed to it; whether the gas has been turned out, or the door locked, or the heat regulated, has haunted most of us. I know a bank officer who, in receiving money, often counts it over two or three times oftener than would appear to be demanded by a reasonable caution. These doubts may assume such exaggerated forms as to constitute a true insanity, the *folie du doute* of the French. The difference between the minor forms of doubt and the grave forms going to constitute *folie du doute* is, as has been emphasized by Hack Tuke and Hughlings Jackson,[1] one of degree only. I recall a patient who was constantly pestered with doubts of all descriptions. If she was eating, she felt she ought not to be doing so; if sitting, she ought to be standing or walking; if knitting, idle; if in bed, out of it, etc., *ad infinitum*. She could never be addressed without expressing doubts, which were to her a real source of distress. She was, in short, a case of *folie du doute*.

There can now be little doubt that certain crimes are due to sudden impulses which arise in the minds of persons who are not ordinarily regarded as insane, and which the subjects are wholly unable to resist.

Impulses to suicide, or to make assaults, or do deeds of violence, or commit crimes, arise in many persons, and yet do not result in action—are not obeyed because they are put in subjection, so to speak, by the inhibitory forces of the mind. When an impulse to commit crime arises and the inhibition to check it is insufficient, the crime is committed. This is the philosophy of the suicidal and homicidal impulse. "Pinel and Esquirol at first doubted the existence of pure insane impulse apart from intellectual flaw or delusion, and many authorities of repute have since their day considered the doctrine a dangerous as well as a fallacious one; yet eventually Pinel and Esquirol asserted the existence of this terrible malady and painted its distinctive features in no uncertain colors." Bevan Lewis, from whom I quote these words,[2] and Maudsley, are both firm believers in irresponsible, impulsive crime.

The simpler forms of impulses, doubts, and fears cannot, as I have said, be regarded as abnormal. In certain individuals, however, they may be so strong or persistent as to be distinctly morbid. For instance, the impulse to touch fence-posts might be obeyed, without exciting comment, by a person passing along a quiet country road and successfully resisted without great effort, when under other circumstances these actions would excite astonishment or subject him to ridicule. On the other hand, if he acted on the impulse, being unable to resist it, while walking with friends in city streets, the impulse would be distinctly abnormal. It might be present in the absence of any other abnormal manifestation of the mind. We must admit with Hack Tuke and Mercier,[1] I believe, as in the example given, that there are diseases of the mind other than insanity; in other words, to say that an individual has some abnormality of his mind is not equivalent to saying that he is insane.

From the fact that these morbid impulses, fears, and doubts are so frequently seen in those undoubtedly insane, and especially in the degenerative types of insanity, such as paranoia,[2] it seems likely, as suggested by Savage,[3] that most frequently in those cases where imperative conceptions appear as an isolated symptom they are the outgrowth of a neuropathic soil; they are marks of degeneracy. They may be in abeyance for years and brought to the surface by shock or disease, lowering vital tone, probably by lessening the inhibitory powers, and in other ways interfering with the association of centres in what Hughlings Jackson calls the upper range. "The man who to-day is conscious of and smiles at an imperative idea gravely believes it to-morrow and labors under a systematized delusion."[4]

With this brief survey of the subject of imperative conceptions in general, I propose to ask your attention to them as a symptom of neurasthenia.

Certain insanities, such as melancholia, mania, paranoia, and paralytic dementia, may develop upon a neurasthenic basis, as has been so well shown by Kirchhoff.[5] Neurasthenia may have been an early stage of insanity, or the mental symptoms may have been developed *pari passu* with the neurasthenic ones; but in either case it is of prime importance to recognize the neurasthenic condition. From the exhaustion, starvation, and poisoning of nerve-centres, which I take to be the basis of neurasthenia, arise many mental symptoms. These have been ably discussed by Cowles.[6] In individuals in whom there is a slight or latent tendency to imperative conceptions it is reasonable to suppose that they might become prominent upon the super-

vention of the underlying conditions which produce neurasthenia. Indeed, in certain individuals where the conditions favor it, a morbid impulse or fear may appear suddenly and be the dominant feature in neurasthenia, as, for example, in this case:

A hard-working, robust-looking, professional man, aged twenty-nine years, was sent to me by Dr. W. F. Robeson last spring. Six weeks before, while sitting in the first balcony at the theatre, he experienced suddenly a strong impulse to precipitate himself below. In great fear and agony he left the theatre lest he should act upon the impulse The next day he felt strongly impelled to break all the china upon the table. After this he was seized with many imperative conceptions, and his life was one of great distress to him, as he feared he was going insane. Examination revealed a long train of neurasthenic symptoms: headache, morning-tire, loss of endurance, irritability, insomnia, etc. He had worked very hard, frequently over-taxing himself, mentally and physically, since boyhood, and while he suffered from some of these neurasthenic symptoms prior to the appearance of the sudden impulse and fear which came to him in the theatre, yet they were not marked, and he had almost wholly ignored them, and had in nowise drawn less on his nervous force in the prosecution of his work; but with the advent of these imperative conceptions his other neurasthenic symptoms became marked, and it was not difficult to discover them when I first saw him, and hence to recognize the morbid impulses and fears as belonging to them.

The case is an illustration of how the onset of neurasthenia may be apparently sudden. In some cases, where the output of nervous energy is greater than the ordinary process of recuperation, there is apparently some compensatory action for a time, just as we see in valvular heart-disease; but a time comes when compensation cannot keep pace with the extra demands, and the break may be, as in valvular heart-disease, sudden and alarming.

Firm assurances as to the absence of organic diseases and the harmlessness of these imperative conceptions, if the will-power were brought to bear, coupled with a semi-rest treatment, hydrotherapy, faradism, tonics, and occasional hypnotics, brought about in the course of six months a restoration to health. Several relapses, however, occurred, and for a time the patient was frequently seized with imperative conceptions of one sort or other; but with the assurances he had received they caused him much less fear. The most persistent of these impulses was to cast himself from a great height. For a time he feared to cross a river bridge lest he should give way to the impulse to jump over, or in crossing he would, at times, avoid the foot-path and walk in the wagon-track.

An instance showing the appearance of morbid fears in a well-established case of neurasthenia is seen in the following case:

M. C., a well-built, tall man, aged thirty-six years, an engineer, of good habits, was referred to me by Dr. J. D. Shull, of Derry, in June, 1892. Mr. C. had in the previous February been prostrated by a severe attack of influenza, following which he had suffered up to the time I saw him from marked neurasthenic symptoms, such as mental depression, insomnia, dull occipital headache, general muscular weakness, vertigo, flushings, tingling, muscular twitching, and constipation. After these symptoms had become established he began to suffer shortly before I saw him with morbid fears. Although long accustomed to his work he began to dread a wreck of his train. This feeling, he explained to me was, he knew very well, altogether groundless. Yet this fear came to him frequently and suddenly, causing him the most acute distress. It often caused him to turn pale and perspire, and on several occasions he called on the fireman to relieve him temporarily, feeling unfit to be at his post. He debated with himself whether it was not his duty to resign his position, and asked my counsel in the matter.

A plan of treatment similar to that pursued in the first case was instituted, and after several months he reported himself as restored to health.

The development of these morbid fears in a man suffering from a severe train of neurasthenic symptoms and their disappearance together with his other symptoms, leave, I think, little doubt that they resulted from the underlying condition of his nervous centres which had produced the other neurasthenic symptoms and of which they were only a part.

In all cases presenting the symptom of imperative conceptions it is highly important to make a careful search for neurasthenia and to determine, if possible, whether they be not an expression of this condition.

The prognosis of imperative conceptions is best when they result from the neurasthenic state. Speaking of them in a general way Savage[1] expresses the belief that they are incurable if they have existed more than a year, and he allowed only slight hope when they are acute or associated with any special cause or period of life. The experience taught by the two cases cited, however, would strongly indicate that the prognosis is good when they are associated with such a "special cause" as the neurasthenic condition. Probably the prognosis is as gloomy as painted by Savage when the isolated symptom is observed in a neuropathic subject.

Scant reference to the relationship between imperative conceptions and the neurasthenic states is made in works on medicine or neurology. In some of the more recent text-books on nervous diseases, however, as, for instance, in that edited by Dr.

[1] Op. cit.

Dercum,[1] in the excellent chapter on neurasthenia written by him, the subject receives a mention somewhat commensurate with its importance. No treatment of the subject of neurasthenia can be considered complete which omits mention of imperative conceptions as a symptom.

CLINICAL LECTURE.

BLEPHAROPLASTY, STRICTURE OF THE ŒSOPHAGUS, EPITHELIOMA OF LIP, SYNDACTYLUS, SUBDURAL CLOT.

Clinical Lecture delivered at the Buffalo General Hospital.

BY ROSWELL PARK, A.M., M.D.

CASE I.—About ten days ago I performed a plastic operation on this girl's face in order to make a new upper and lower eyelid. Whereas formerly she even slept with the eye open, she can now close the lids. The upper lid was taken from the temporal region, the lower from a V-shaped incision in the cheek. The upper wound was closed by collateral incisions and sliding of tissues, while the lower gap was closed as a linear wound. The scars are at present very noticeable, but they will fade in time.

CASE II.—This patient, an old man, has stricture of the œsophagus, and he is slowly starving to death; have proposed performing gastrostomy, but he positively declines operation. Seeing the end of life approaching he has yielded so far as to permit me to try electrolysis within the œsophagus. This is a procedure in which I have little confidence, but I shall put it in practice in order to do all possible for the patient's relief and with the hope that if this fails he will consent to surgical measures. The flexible œsophageal electrode is connected with the negative pole of the battery, and a current of twenty milliampères is passed for five minutes. We will repeat this every day.

CASE III.—The first operative case is that of a man of fifty-five years, who comes in with an ulcer on the lower lip, not quite in the middle line. It has an indurated base, which flares out so as to make the lip thicker than it should be. The area of infiltration shades gradually into normal tissue. There is no difficulty in making a diagnosis of epithelioma, from the age of the patient, the location of the sore, the refusal to heal itself, and the obvious presence of constant irritation of a pipe. This form of cancer has been called pipe-smokers' cancer. The teeth are badly decayed, foul, and covered with a carbonaceous deposit. There is a notch on the side of the cancer showing where the pipe-stem has habitually rested. The patient has unwittingly favored the growth of the cancer by a variety of applications which he has made. He has also relied on clover tea, and has only sought professional advice within the last few days, when the outlook, though not hopeless, is unfavorable. Epithelioma in this location is almost always seen in men of middle or advanced age; yet not long ago I had to operate on a young woman of twenty-eight who had as typical an epithelioma of the lip as this.

So far as I can feel, there is no lymphatic involvement; perhaps after the patient is anæsthetized I may be able to find enlarged lymph-nodes, and then it will be necessary to remove them. I have often told you that in operating for cancer you must remove all tissue that is invaded without false mercy, stopping only at organs essential to life. The operation consists in the exsection of a V-shaped piece of the lower lip, and, as the closing of this wound reduces the lower lip so that there is a relative redundancy of upper lip, I shall extend the mouth laterally and close this incision by a sliding of tissues, so as to equalize the two lips. This makes the operation longer and bloodier, but the cosmetic effect is better.

It has been customary to dress such wounds with collodion, since the ordinary antiseptic dressing is out of the question; but I have noticed that a little saliva usually works its way under the crust, or else the collodion is raised by an effusion of serum, bacteria enter, and suppuration ensues. Therefore for the last few years I have adopted the policy of allowing the line of sutures to be covered with a scab of blood, perhaps using a little collodion after a day or two, but not at first.

CASE IV.—This case is one of inguinal hernia, of short duration, in a man of thirty-two years. The tumor is only about as large as a hen's egg when the hernia is down. The intestine is now in the abdominal cavity. Having had the site of operation shaved, scrubbed, and disinfected, and surrounding parts shut off by damp bichloride towels, I shall proceed to cut down over the external inguinal ring. There is undoubtedly a serous sac, and the search for this is not quite so easy as it would be with the hernia unreduced. I shall look for it alongside the spermatic cord, which is easily felt. Having found and isolated the sac, I shall now carry out Kocher's idea, make an opening at the upper end of the inguinal canal, draw the sac up into the opening, and twist it. If this does not make a radical cure of the condition, I do not know what will. The outer wound is closed with a continuous subcutaneous catgut suture. Although it is not so important in this location, the subcutaneous suture has the advantage over the ordinary puncturing suture of leaving no cross-marks, so that after healing only a linear scar is visible.

CASE V.—This is morphologically an interesting case, that of a little child, with the middle and ring fingers of the right hand united, and with the middle, ring, and little fingers of the left hand webbed together, with a supernumerary finger between the last two. This condition is known to the laity as web-fingers, technically as syndactylus. Sometimes one sees a complete webbing of all the fingers, when the hand looks as if it were covered with a skin mitten. The condition is an evolutionary relic, a reversion to the condition of united phalanges as seen in many of the lower animals. The condition normally disappears early in the life of the human fœtus. There is nothing difficult about the diagnosis, and the general indication for treatment is plain, for parents do not wish this interesting condition to remain. The separation of the fingers is not, however, so easy as the separation of two pieces of candy that have become stuck together, and it is not sufficient simply to make longitudinal incisions without preventing the raw surfaces from again cohering. Whenever possible we make an oblique compound dissection between the bones, so that there remains on each finger a thin flap which can be wrapped around and sutured to the

[1] Nervous Diseases, by American Authors, p. 65.

skin on the opposite side. Sometimes there is not enough skin to permit this, and then we must simply spread the bones apart and pack in enough antiseptic material to prevent adhesion, and allow the surface to heal by granulation and subsequent cicatrization. A condition resembling syndactylus may be seen from burns or other traumatism and ulceration. When the syndactylus is congenital, it is an advantage to operate as early as possible, for parts thus bound together do not grow so rapidly as those which are free to move.

Supernumerary fingers are not uncommonly seen on the outside of the hand. Sometimes there will be two thumbs or a bifid terminal phalanx of the thumb. Similarly there may be two quite perfect little fingers or the sixth finger may hang like a flail on the little finger. This is a relic of the time when some animals had six digits. No congenital defect or anomaly is ever found which has not its analogue or explanation either in fœtal life or in some of the lower forms of the animal kingdom.

On the right hand I am having some difficulty in coaptating the skin about the little finger. On the left hand the removal of the supernumerary digit will allow plenty of tissue to cover the little finger. It will be interesting to note whether Nature, in supplying an extra finger, has provided it with flexor and extensor tendons. Such proves to be the case. The extra finger is smaller than the others and its bones are more slender. There are only five metacarpal bones, the extra finger sharing the articulation of the little finger. To-day I shall not try to separate the ring and middle fingers, but will wait till the wounds on the adjacent sides of the ring and the little finger have healed. The skin-flaps are sutured, the parts are anointed with antiseptic vaseline which has also been sterilized by heat, iodoform is dusted on, and the fingers are separated with iodoform gauze.

CASE VI.—This patient is a young man who fell on the sidewalk night before last, striking the back of the head. He was quite rational until last night, when he began to talk strangely and to make queer movements of the arms and thorax, and then he had a shivering of the entire body. Before the clinic I could get no answer to my questions, and I concluded that he was aphasic. Since then he has spoken brokenly and without finishing his sentences. His right arm seemed to be in a cataleptic state, staying wherever I put it. While waiting in the anæsthetic room he has had two convulsions, and on account of the irritative character of the symptoms I believe that the lesion is cortical and superficial, and having come on after an interval it is probably of the nature of a hemorrhage.

On inspecting the head since it has been shaved, I note a recent bruise in the middle line, a little above the occipital protuberance. A blood-clot here would not account for his symptoms, especially not for the interference with speech. I shall, therefore, trephine over the motor area of the left side of the brain, following symptoms rather than external appearances. A semi-elliptical incision exposes the left parietal region. The periosteum is retracted, and a chisel-wound made to catch the centre-pin of the trephine. I have endeavored to approximate the speech-centre, not by measuring by a scale, but from a general remembrance of anatomy. If the clot is large enough to require removal, I can get near enough to it in this way, and we almost always have to enlarge an opening after finding a clot, in order to meet particular indications. So far the operation is purely exploratory. It is possible that a localized meningitis could have produced some of the phenomena noted here, but hardly the aphasia. The patient's skull is thick—though this is no index as to his mental abilities. The dura is not bulging, but it is discolored by a clot beneath, and on incising it the clot is gradually pushed out by the pulsations of the brain. The clot is quite tenacious, showing that it is not very fresh. I have caught a small bleeding vessel with a hæmostat. Further oozing I shall endeavor to check by using this antipyrin spray. The clot is removed partly by the sharp spoon and partly by wiping with aseptic gauze, which has almost supplemented the sponge in modern surgery, the latter being so difficult to render aseptic.

I am glad to give Dr. Weidenbauer credit for sending this case to the hospital. He recognized the condition present, realized the importance of surgical relief, and has done everything possible except performing the mechanical part of the treatment.

It is quite probable that as the patient recovers from the anæsthetic, the relief of pressure will be manifested by speech and the rapid recovery of consciousness. The wound is dressed antiseptically, without complete closure of the scalp-wound, as we wish to provide for the easy evacuation of any further blood-clots that may be formed.

CLINICAL MEMORANDA.

CASE OF TRAUMATIC SEPTIC MENINGITIS. TREPHINING. TEMPORARY RECOVERY, FOLLOWED BY LARGE ABSCESS OF BRAIN.

BY ANDREW J. McCOSH, M.D.,
OF NEW YORK.

THE following case is of interest for three reasons: First, the marked improvement which followed the opening of the skull and drainage of the meninges, resulting apparently in cure or at least in the temporary recovery of the patient. Second, the persistence of the sepsis within the cranium for a period of four months without constitutional or local manifestations. This was proved by the presence of the same species of bacilli at the two operations. Third, the existence of an enormous cerebral abscess (eight ounces) and the absence of grave symptoms. There were no paralysis, no convulsions, no delirium or subnormal temperature, neither was there marked elevation of temperature. The only symptoms were moderate pain, a slight stupidity, and finally vomiting, but for ten days or more the patient had walked about as usual, had eaten with a good appetite, and had been fairly intelligent in spite of the presence of a large collection of pus in his brain. The fatal result due to pneumonia is another example of the close connection between sepsis in the brain and sepsis in the lungs.

H. H., aged thirty years, was struck or kicked on the forehead in a fight on *October 1, 1894*. He walked home, and made no special complaint until the following day, when he suffered from headache in the frontal and parietal regions, and felt so feverish and weak that he remained in bed. Toward evening he became

restless. On the following morning (*October 3d*) he was rather apathetic, and his restlessness had increased. His symptoms became worse during the day, and in the evening he was brought to the hospital in the ambulance. On admission he was stupid and complained of severe headache. Temperature 102°, pulse 80, respiration 30. The pupils were contracted and regular. There was no paralysis. At times he was very restless. Knee-jerks unaltered.

4th. Stupor had increased. He could be aroused with difficulty, and would then moan and show great irritability for a few minutes and again lapse into stupor. Temperature 100°, pulse 44 to 58, respiration 16. Operation was advised, as it was thought that there was a blood-clot pressing on the brain and probably a meningitis.

5th. Complete coma. Temperature 101°, pulse 40 to 50. Consent to operation was obtained.

Operation, October 5th. Chloroform. A semicircular flap with the apex just above the brain-line was dissected downward and the frontal bone exposed. A linear fracture one and one-half inches long was seen running in a vertical direction from left to right almost over the longitudinal sinus. There was no depression of bone. A one-inch trephine was applied just to the right of the median line, and on removing a button of bone an extradural blood-clot was seen alongside of the longitudinal sinus and evidently caused by a rupture of its wall. The opening was enlarged by rongeur (Lüer) forceps. On removing the clot the hemorrhage from the sinus started afresh, but was easily controlled by pressure. When the dura was exposed it was seen that there was no pulsation. As soon as the knife punctured this membrane a stream of turbid serum spurted out with considerable force. Two ounces of fluid escaped. Another blood-clot was found under the dura, and it was scraped away. The pia mater was then seen to be gray, cloudy, and without lustre, and was in astate of inflammation. Another trephine-opening for the sake of drainage was made over the left frontal eminence, and in this side there was also found both an extradural and intradural blood-clot. Irrigation with salt solution was employed. Horsehair-drains were inserted inside the dura through each opening. The scalp-flap was loosely fastened in place by a few sutures and strips of gauze inserted on each side. During the operation the pulse had risen from 38 to 85. The bacteriological examination of the fluid showed numerous colonies of streptococci and staphylococci.

6th. Coma not complete. He could be aroused, and he began to be delirious. Temperature 100° to 102°, pulse 86 to 100, respiration 24.

7th. Very noisy and delirious. Temperature 101° to 102½°, pulse 80 to 90, respiration 18.

During the first week after the operation he continued very noisy with almost constant delirium. Temperature 100° to 102°, pulse 75 to 80.

The wound was dressed on the fifth day, and the dressings found soaked with considerable serous discharge.

Second week (*October 12th to 19th*) there was but little change. Temperature ranged between 100° and 102°, pulse 80 to 100.

Third week (*October 20th to 27th*) there was a slight improvement. The temperature was lower—99½° to 101°. The pulse varied between 80 and 100. At times he talked intelligently, and would answer questions, though for the greater part of the time he was noisy and delirious.

Fourth and fifth weeks (*October 28th to November 12th*) improvement continued in his mental condition, but not in temperature. During the day he was comparatively quiet, though often irrational, and always noisy at night.

Sixth to eighth weeks (*November 12th to December 3d*) his mind gradually became clearer, he talked intelligently with his friends, and manifested interest in his surroundings. At night he was still restless. Temperature remained between 100° and 102°.

On *December 6th* he was out of bed, and soon began to move about the ward. His memory was not good, his mental movements were sluggish, and he was still occasionally irrational at night. After *December 11th* his temperature remained below 99½°.

On *December 24th* his fever had entirely disappeared. Appetite good. No headache. Wound completely healed. Discharged apparently cured. Two weeks later he returned to the hospital on a visit, and talked intelligently with the patients, and, while somewhat sluggish yet, he seemed comparatively well mentally and physically. For four months after he left the hospital he was entirely free from pain, fever, or sign of mental aberration. He was able to do light work, and seemed happy, though his wife noticed some loss of memory and occasional attacks of stupidity or indifference to his surroundings. About the first of April he began to complain of pain in the region of the right trephine-opening, and noticed a bulging outward of each opening. A few days later he felt sharp pain in his right eye, and also some pain on the left side of the frontal region. He also appeared rather stupid. He was readmitted to the hospital on *April 15, 1895*. He complained of severe pain in the right eye, over the right trephine-opening, where there was a pulsating swelling the size of a small egg. There were also a bulging of the left trephine-opening and some pain in the left eye. Pressure on the projecting masses increased the pain in his eye and produced dizziness. There was no paralysis of motion or sensation. The patient walked about the ward, and conversed intelligently, though his reasoning-power was slow in its action. He was not restless, but was rather torpid. Temperature 98½°, pulse 100, respiration 24.

Diagnosis, probable cerebral abscess.

16th. Temperature 99°, pulse 70 to 80. Pain less severe when he remained in bed.

17th. Temperature 99° to 99½°, pulse 80 to 96, respiration 20. Complains he cannot sleep.

18th. Patient walked over to the dispensary and back (quarter of a mile) for an examination of his eyes. Slight congestion of the right fundus was found. Temperature 99½°, pulse 80 to 90. Pain more severe. Vomited several times.

19th. Vomiting. Bulging through trephine-openings increased. Stupidity more marked. No paralysis. When spoken to answers questions intelligently. Special senses not affected. Pupils react regularly. Knee-reflexes lost.

20th. Operation. Chloroform-anæsthesia. A semilinear skin-flap was dissected from the frontal bone and

from the dura mater which bulged out of the trephine-opening, to which the flap was very adherent. The dura was much thickened. An aspirating-needle passed into the brain-substance drew out pus. The dura was incised around the upper margin of the right opening, and under it was found brain-tissue mixed with granulations. This was scraped away with a sharp spoon, and immediately a jet of thick greenish pus spurted out to the distance of two feet. The opening in the brain was enlarged, and the pus continued to flow until eight ounces had escaped. It was then seen that the bulging over the left trephine-opening had collapsed. The finger passed into the abscess-cavity found it lined with a smooth, uniform membrane which bled but slightly. The cavity was as large as a man's fist, and occupied apparently the entire frontal lobe on the right side, with the exception of a thin shell of cerebral tissue which formed its wall. The cavity also extended into the left frontal lobe. The dura was opened on this side, and the finger thrust through a thin layer of granulating cerebral tissue passed into the abscess-cavity. This was then gently washed out with boric-acid solution, and drained through each trephine-opening by a rubber tube and strips of gauze.

Before the operation, temperature 99½°, pulse 80. Two hours after operation temperature 102°, pulse 120.

21st. Temperature 100° to 102°, pulse 80 to 100, respiration 16 to 20. Free from pain. Mind brighter.

22d. Temperature 100° to 101°, pulse 90. No paralysis. No vomiting. Rather restless. Wound dressed.

23d. Temperature 100°, pulse 80 to 90. Takes more interest in surroundings. No pain.

24th to May 8th. Temperature 100° to 101°, pulse 80 to 100. Occasionally very restless. Takes nourishment. No paralysis. Hernia cerebri springing out of wound. Very little discharge.

9th to June 1st. Temperature 100°, pulse 90 to 110. Mental state more clouded. Some weakness. Occasional delirium. Gradual loss of strength. Hernia cerebri increases in size in spite of frequent clippings.

1st to 7th. Patient somnolent. Refuses food. Delirious at night. Decidedly weaker. Temperature 101°, pulse 88–100.

8th. Distinct change. Unconscious. Temperature 104½°, pulse 120, respiration 36. Labored breathing. Unable to swallow.

9th. Temperature 106°, pulse 120, respiration 40. Comatose. Died in the afternoon.

REPORT OF AUTOPSY BY DR. J. S. THACHER.

Brain. Abscess-cavity size of fist occupies most of right frontal lobe back to about one inch in front of fissure of Rolando. Wall in front is a thin membrane which becomes gradually reinforced with brain-tissue. The whole anterior part of the right hemisphere was enlarged at the expense of the right temporal lobe and of the left frontal lobe. On microscopical examination abscess-wall composed of granulation-tissue, simple inflammation. A few pea-sized spots of suppuration at tip of left frontal lobe.

Lungs. Consolidation of apex of lower lobe of left lung; other patches scattered through the upper and lower lobes. In right lung patches of pneumonia distributed as in left.

A CASE OF CONGENITAL OCCLUSION OF THE COLON AT THE ILEOCÆCAL VALVE.

BY CARL WEILAND, M.D.,
OF PHILADELPHIA.

As cases of congenital occlusion of the intestine are very rare, only two such cases in 111,451 patients having been recorded at the Vienna Foundling Hospital, according to E. Theremin,[1] it would seem of interest to put on record the following example of this hemiteratic anomaly:

On October 26, 1895, at 2 P.M., Mrs. Wr., primipara, aged thirty-four years, of Philadelphia, gave birth at full term to a boy of apparently perfect development. Nothing unusual was observed in the infant until October 27th, at 1 A.M., when the child began to vomit a darkish fluid which left only a light-colored stain on the clothing. As the child had been given some tea of a similar color it was supposed to be that; at any rate, no pathognomonic odor could be detected. This vomiting occurred on that day whenever the child was given some nourishment. As toward evening the bowels had not moved, in spite of a little piece of soap that had been put into the rectum, an injection of lukewarm water with a little soap was given, which returned immediately and brought small cylindrical masses of white mucus about 5 mm. in diameter. This, of course, aroused suspicion at once; but the next morning conclusive evidence of an internal pathological condition was furnished by the vomited matter, which now was distinctly fecal in odor and had the appearance of meconium. As the first thought was that of intussusception a soft-rubber catheter was introduced into the rectum, which could be pushed up about eight inches. Then the nates of the child, who was already very weak, were raised and plain lukewarm water was injected with a Davidson syringe. As the injection returned at once, the anus was gently compressed, and about two ounces of water were again injected. This procedure increased the vomiting of fecal matter very much, and so was stopped at once; but the vomiting continued, respiration became embarrassed, and soon the child died, about forty-eight hours after birth. One hour later Dr. U. W. Vollmer kindly assisted me in making the post-mortem examination, which showed the following condition of the intestinal tract:

The small intestine showed great vascular injection and was much distended with gas, especially near the ileocæcal valve. Here the diameter of this viscus was about 18 mm., the same as that of the caput cæcum, with which the small intestine was continuous, as the lower fold of the ileocæcal valve was absent or, rather, very little developed. The upper part, however, of this valve, the ileocolic fold, was developed too much, for it stretched across the whole lumen of the bowel and formed a complete septum between the colon on the one side and the cæcum with vermiform appendix and small intestine on the other side. There was not the slightest chance for a communication between these two parts. Below this anomalous diaphragm the cæcum and small intestine showed well-developed villi, and the entire mucous membrane was stained brown with biliary pigment and showed a small amount of

[1] Deutsche Zeitschrift für Chirurgie, 1877, Bd. viii.

meconium. Above the abnormal septum the large intestine was very much contracted, having a diameter of only 5 mm. It also had no ascending part, but the transverse colon turned back at once to the posterior aspect of the abdominal cavity and ran transversely as far as the usual position of the splenic flexure, where the descending colon commenced. The whole colon and rectum, about ten inches in length, contained only soft, white mucus, and not the slightest trace of meconium. Its surface looked white compared with the color of the small intestine, and its walls were thin, having apparently been arrested in its development.

The time when the septum must have formed we can fix, with great probability, as follows: As meconium appears in the intestine about the end of the fourth month of intrauterine life, and as no meconium was present in the large intestine, it is evident that the septum must have formed before the end of the fourth month. On the other hand, it is known that the transverse colon is developed at the third month, and the ascending colon at the fifth month, from which would follow that the large intestine of this case was arrested in its development at about the fourth month. If we further assume, as would seem justified, that both phenomena, the appearance of the septum and the arrest of development of the colon, had *one* underlying cause and occurred at the same time, we come to the probable conclusion that we had to deal with an infant born with a rudimentary colon and a total occlusion of the intestine which had formed at the fourth month of intrauterine life.

FOREIGN BODIES IN THE EAR.

BY ROBERT BARCLAY, A.M., M.D.,
OF ST. LOUIS;
AURAL SURGEON, ST. LOUIS CITY HOSPITAL, ETC.

THE circumstances and phenomena attending the presence of a foreign body within the external auditory canal are so many and so varied that the condition seems to present endless curious and instructive features. Three cases recently met with seem to possess such features sufficiently unique to entitle them to the consideration of the intelligent readers of THE MEDICAL NEWS, than whose columns can be found a no more lasting nor well-known nook for the preservation of clinical *memorabilia*.

"Invisible hairpin," broken, and caught within ear.—A rare case of ensnared aural foreign body is that of a lady, aged about forty years, who, while "picking" her left ear with a so-called "invisible hairpin," several hours before the consultation, had heard a sudden "twang" and sticking in the ear, as if the hairpin had broken. And so, indeed, it had done; for on the instant as she, startled, had attempted to jerk it quickly from the ear, the sharp extremity of the inner portion of its lower prong sprang away from its fellow, penetrated the soft tissues of the floor of the external auditory canal, and remained imbedded there; the separated end of this prong only coming away in her grasp. Every attempt on her part to remove the hairpin by traction on its projecting prong—she durst not force it *inward* for fear of wounding the drumhead—had served but to bury the point of the broken prong more deeply into the flesh of the canal, thereby increasing her suffering. Advised by her family physician not to delay, she forthwith sought advice and aid.

On examination, it was found that the lower prong of the "invisible hairpin" had broken at the outer end of its wavy portion, and seemed firmly imbedded in the floor of the auditory canal, now quite inflamed, at a point about one-third of its depth from the outlet of the canal. The loop or turn of the hairpin was about one-half inch from the flaccid portion of the drumhead; and together with the unbroken prong, it lay closely against the roof of the canal. Projecting from the meatus there was enough of this prong to be easily grasped between one's thumb and finger.

Removal of the hairpin was effected by first inserting within the meatus a Gruber speculum, encircling the unbroken projecting prong, and then raising the end of the broken one with a long-shanked aural hook, when the hairpin was readily withdrawn.

Under one or two applications of a vulnerary, the wound of the canal floor promptly healed.

Characteristic effects of bird-shot thrown into an upturned ear. CASE No. 103,672.—One morning as this young clerk, aged eighteen years, was lying upon his left side, facing the wall, his cousin, from a distance of seven feet, playfully pitched a few—say, ten or twelve—bird-shot onto his right ear and face. He felt shot enter the ear and deafen him temporarily; and on turning this right ear downward saw three shot roll out. There was now no pain nor tinnitus; but the ear felt stopped up, "a stuffiness, not a decided deafness," which "opened up whenever he swallowed." Slight headache came on toward evening, but disappeared during sleep. Upon awakening the following morning another shot rolled out of this ear. This settled his determination to consult his physician, who at once referred him to me.

On examination, his right drumhead was found a trifle congested, but otherwise normal.

A mild tympanic inflation, together with mercurial aperient, effected complete relief from his aural symptom.

Hard foreign body adherent to the drumhead. CASE No. 103,687.—A curious instance of foreign body upon the drumhead was that of a retired capitalist, an American, aged forty-six years, who for two weeks had suffered from deafness on the left side, with occasional tinnitus, but without earache. One month before he had had a severe attack of acute coryza, for which he had sniffed up some "Pond's extract of witchhazel," blowing his nose immediately thereafter. Upon development of his aural symptoms, of which pain was one at the onset, leeches had been applied about his auricle, and for two days, morning and evening, for about twenty minutes his ear had been douched with hot water.

At the time of our consultation he could hear with the affected ear a forty-eight-inch watch on contact only, and low voice and whisper at a distance of fifteen feet.

On examination of the left ear the vibrating portion of the drumhead appeared thickened, opaque, lustreless, and somewhat retracted; the flaccid portion and entire periphery much congested, and the short-process of the handle of the malleus barely recognizable. Just in front of the handle, however, was a dark body, resembling a dried blood-clot, but thicker. This was about three-sixteenths of an inch long, one-sixteenth inch in diameter,

apparently roughly cylindrical in form, and parallel to, and as if closely adherent to the handle of the malleus.

Removed with Sexton's foreign-body hooked curette, it proved to be a heavy, very hard, brownish-black mass. Its nature has not yet been determined, but it is supposed to be a coal-cinder.

After its removal the tympanum was inflated by Politzer's method, when testing proved the hearing for the forty-eight-inch watch to be as high as one-eighth of an inch.

He made a rapid recovery.

MEDICAL PROGRESS.

Syphilitic Gummata of the Heart.—During a recent meeting of the Montreal Medico-Chirurgical Society (*Montreal Med. Journ.*, vol. xxiv. p. 474) Dr. Finley presented the report of a case of syphilitic gummata of the heart and liver, and exhibited the pathological specimens showing the characteristic lesions.

Tetanus Treated with Antitoxin.—E. H. Howlett, F.R.C.S., reports (*Med. Chronicle*, vol. iv. p. 186) a case of tetanus in a lad of fourteen years, arising about two weeks after the receipt of gunshot-wounds in the legs. The repeated administration of antitetanic serum produced no immediate effect upon either the spasms or the general condition of the patient, but rapid improvement took place in the appearance of the wounds. Convalescence was established in twelve days.

Why is the Abdomen Opened in the Middle Line?—Dr. F. Winson Ramsay (*Lancet*, No. 3370, p. 1355) asks this pertinent question, and refers to the unanimity of operators in this selection. The usual reasons given for preference for the median incision are (1) less hemorrhage; (2) fewer important structures to encounter; and (3) easy access to all parts of the cavity. These Dr. Ramsay considers imaginary and really points of disadvantage. In the first place, the matter of hemorrhage, there is no reason to fear troublesome bleeding in any part of the abdominal wall, and if slight in the linea alba, it shows a lower vitality there, and hence a delayed or imperfect union may result. Secondly, the whole depth of the incision being through fibrous or tendinous tissue the young operator may enter the cavity unexpectedly, injuring its contents, and in closing the wound he will find difficulty in readjusting the several layers as accurately as if they were distinctly separated by muscular tissue, etc. Thirdly, the greater facility afforded in exploring all parts of the cavity is overestimated, and more than outweighed by the presence of the umbilicus immediately in the way when it becomes necessary to extend the incision upward. To render the umbilicus strictly aseptic is a difficult, if not impossible, task.

The writer suggests that abdominal section be made vertically through the rectus muscle on either side, and contends that here the operator will meet all of the advantages and encounter none of the disadvantages mentioned above. He has recently put it to a practical test in five operations, and is convinced that its advantages are not alone a matter of theory, but real.

Some of the Immediate Results Produced by Castration in Cases of Enlargement of the Prostate.—Dr. C. W. Munsell Moullin (*Lancet*, No. 3770, p. 1347) calls attention to an unexpected immediate effect following castration, to wit, the recovery of power to void the urine naturally ofttimes within the first few hours after the operation. Sometimes this has remained permanent, but usually there is a temporary relapse. He cites many cases illustrating this point, one of which was observed by Mr. Hunt, of Wolverhampton, wherein micturition was naturally performed two hours after the operation, and continued so for five days, when the use of the catheter had to be resumed. An item of especial interest in this case was a tonic spasm of the muscles about the anus, lasting for some time, quite the opposite having been their condition previous to the castration.

Clearly this rather astonishing result cannot be explained upon the ground of atrophic changes in the gland, even though they appear after six or eight days. Nor will the feature of rest in bed, etc., be counted as a factor, for in most instances this is part of the preparatory treatment. Prof. White accounts for this by early changes in the median lobe of the body, which is so prone to act as a valvular obstruction; but this is obviously faulty, for time enough has not elapsed for any real diminution in its size, although atrophic changes are known to begin in the organs within a very few days; and, further, such decrease in size, did it occur so early, should be permanent, which will not explain the period of relapse so common in the progress of these cases.

In the estimation of Dr. Moullin, the only reasonable explanation lies in the active stimulation produced by ligature of the spermatic plexus upon the vessel-walls, as well as the voluntary muscular tissue throughout the pelvis—as exemplified by Mr. Hunt's case cited above. The sudden and active stimulation of these nerve-trunks by ligation is certainly capable of producing just such results as have been observed, and their gradual subsidence will also coincide with the gradual adjustment of the injured nerves to the new conditions.

THERAPEUTIC NOTES.

Permanganate of Calcium.—Nardas (*Gaz. Méd. de Paris*) speaks of the superior power of oxidizing possessed by this substance. When brought in contact with organic matter it is at once resolved into manganese dioxide and lime, giving off oxygen. Experiments prove it to be superior to bichloride of mercury and quite free from toxic or caustic properties.

For Diphtheria—

THE STATUS OF THE MEDICAL ARM OF THE SERVICE IN CASE OF WAR.

HAPPILY the war-cloud has blown over. We draw a sigh of relief as we think of the ills that threatened us for the moment which, for the present at least, have vanished. War may mean glory and renown and countless heroes; it may also mean defeat and disgrace; it always means desolation, sorrow, and horrors unspeakable.

No one can have a keener conception of the force of these facts than the members of the medical profession, who, in their daily lives, see so much that requires nerve and patience and self-control. At the same time, should the country be imperilled and its existence threatened, there is no class of citizens which would be found more ready to make sacrifices, endure trials, and give their lives if necessary in its behalf.

How was it in the Civil War? The losses by death and disability in the medical corps were relatively greater than in any other arm of the service. On the field of battle the surgeons, although non-combatants, pressed toward the front, regardless of personal safety, and often lost their lives in the absorbing interest of the hour. The motive was not curiosity nor mere recklessness, but the desire to be where the need for their services was greatest. Others were worn out by the strain and fatigue of hospital service. We all know something of the tax which is sometimes imposed by hospital service in civil life; what must it be in time of war, with a hundred imperious demands upon a doctor's time and force at once? Those men who underwent such trying experiences were not mentioned in the reports for special bravery, medals and distinctions were seldom distributed among them, neither did they seek or expect them.

When we remember that at the close of the war there was scarcely a score of medical colleges in the country, that hospital experience prior to the war was limited to a mere handful of those who entered the service, that therapeutics, medical and surgical, was in its infancy compared with its present condition; when we consider, furthermore, the enormous numbers of sick and wounded successfully cared for, medical supplies obtained and distributed, and obstacles overcome in accomplishing these results, the magnitude of the work becomes apparent. To feel the touch of kinship with men of such achievements thrills one with joy and admiration.

The war-cloud has vanished; it is to be hoped it will not again appear above the horizon; if it should, there need be no question as to the loyalty and devotion of the medical corps.

But something more than these sentimental qualities would be required: skill in organizing hospitals, with their complicated equipment and supplies, profound knowledge of military hygiene, ability to organize means for the rapid and easy transportation of the sick and wounded, not alone to the field-hospital, but to the place where treatment, whatever its character may be, will be completed; in a word, all that pertains to the sanitary condition of marching and fighting men, or men in camp, usually grouped together in large bodies, are essential qualifications. That there should be skill and experience in the treatment of disease and injuries goes without saying. Nor is it to be forgotten that good sanitary regulations sometimes decide battles.

How does the present medical situation compare with that which confronted us in 1861? The material and intellectual development of the country during the past thirty years is an answer to the question. Instead of a few medical colleges, none of them of the first rank as we now understand it, we have probably twenty which, as well-equipped centres of

instruction, will compare favorably with similar institutions anywhere in the world. A very much larger number of lower grade colleges, while inferior in their opportunities and advantages, are serving a useful purpose as auxiliary to the others. Hospitals, where there was one at the close of the war there are now a hundred, and if there is anything of value in any hospital on earth that has not been tried in our principal hospitals East and South and West, it is because it has thus far been successfully concealed from inquisitive American eyes. With such colleges and hospitals, with opportunities for culture here ever broadening, and with opportunities for study abroad, of which thousands of the present generation of doctors have availed themselves, and with patriotism and loyalty to duty which are unquestionable, it is not to be doubted that with the first call to arms a medical corps could be quickly organized which would be ample as to quality and personnel for almost any conceivable requirement. Fortunately, too, the head of the medical department of the army at the present time not only reflects lustre upon the army and the country by his scientific achievements, but possesses executive capacity of a rare order, which would enable him to expand the service judiciously in case of need, and distribute to administrative posts the officers of tried experience, some of whom saw service in the Civil War. Of great assistance also would be the medical officers of the national guard, whose experience in the summer camp and whose systematic training of successive ambulance-corps have developed an organization of pronounced efficiency.

The transfer of duties and relations from civil to military life, with its discipline, its subordination to authority, and the other conditions incidental to the life of a soldier, would be found difficult and trying to many men of excellent capacity and great usefulness, who nevertheless chafe under restraint and routine regulations. We would suggest that in the curriculum of our medical colleges a very distinct period be allotted to the study of military surgery and the special duties which pertain to the military surgeon. It would also be well if some extension of the military system were applied to our hospital management, at least in the larger cities, where the hospitals would at once be required for military purposes, and from which the higher medical officers would probably be promptly drawn.

It may not be inappropriate to inquire as to the character of the work of the medical corps if war should occur. An interesting article bearing upon this phase of the subject has recently appeared from the pen of Sir William MacCormac. He speaks of the greater velocity and smaller size of the missiles now in use as necessarily effecting a change in the character of the wounds which would be received and require treatment in war. There would be more penetrating, fewer lacerated and bruising and crushing wounds. The wounds produced by these small missiles, if not instantly fatal, would have small openings of entrance and exit, and would be relatively difficult to treat. There would be fewer coarse wounds of bayonet and sabre, there would certainly be fewer gangrenous wounds, because of antiseptic treatment immediately and universally applied. There would be fewer wounded by whatever means, there would be more killed outright. The improvements in our ambulance-system, the existence of railroads at almost any point in this country, or in any other in which battles are likely to be fought, will greatly simplify the question of transportation of the wounded. If the terrible effectiveness of modern firearms will tend to shorten a war between two great powers because of the losses which one or both would sustain, equally true is it that the resources of modern scientific medicine would permit a larger percentage of the sick and wounded to be quickly restored to duty and effectiveness than at any previous period of history. What a striking contrast these two facts afford, superlative destructiveness on the one hand, superlative beneficence on the other.

WHAT DETERMINES THE LOCALIZATION OF DISEASE?

The accurate localization of disease has been the chief aim and study of the diagnostician during the last fifty years. And wonderful are the advances which its enthusiastic pursuit has led to. Such terms as "general debility," "asthenia," "phlogistic," "bilious," "sanguine," "lymphatic," "amaurosis," "rheum," "decline," etc., have almost disappeared from our vocabulary, and the gain both in clearness of our conceptions of disease and efficiency in combating it has been enormous. In our systems of medicine nowadays almost any disease, except the contagia and the diatheses, is referred to some special organ as the chief seat of its processes; but this wonderful progress has simply been gradually bringing us face to face with another problem behind all this, and of even

greater interest and practical importance, "What determines the localization of disease?" Is it some peculiarity in the organ affected itself, some special pressure of the environment upon it, or some disturbance of the general nutritive balance between all the organs of the body? Or is it some ancestral tendency of the organ or part which lies deeper than any of these? We have only reached the point as yet where we can ask these questions, not answer them, in most cases; but there is one field of research from which are beginning to come some highly interesting and valuable suggestions as to the possible nature of one class of causes of the localization of disease. And this is the rapidly developing department of evolutionary pathology.

From the point of view of this school there is a strong and growing tendency to regard many forms of morbid action as reversion to processes which were normal or physical in these tissues at an earlier stage of their ancestral development. For instance, calcareous degeneration is a "dropping back" to the simpler and easier processes of the coral-polyp or chalk-animalcule (*Globigerina*) stage of our development, fibroid change a sinking on the part of the cells involved to the sponge-level, cancer a "rebellion" of the glandular epithelium, involving a return to the anarchistic "every-cell-for-himself" hydroid stage, gout a falling of the lever and muscle cells in the avian or reptilian stage, in which uric acid is their normal product, etc. According to this suggested theory, any prolonged lowering of the nutrition or vitality of a part or of the entire system, whether from local causes, such as fibrotic arteries, or from general, such as underfeeding, excessive exposure, insufficient supply of oxygen, senile changes, etc., may be sufficient to set up one of these reversionary degenerations and thus account for a large class of disease.

But this cannot be further discussed here, as it is to another suggested factor in the causation or localization of disease we wish specially to call attention. And that is the "age," both embryonic and ancestral, of the organ attacked. It is an accepted rule in both biology and psychology that those parts or properties which are the last to appear in an organism are usually the first to disappear. The flowers of plants, the cells of the brain-cortex, the menstrual function in woman, the highest power of the intellect and imagination, and in a race the higher social virtues and graces, in famine or war, for instance, are illustrative cases. Now, while it is impossible to arrange all the organs of the human body in the exact order of their age or antiquity, yet there are several of them which are obviously much later in the embryologic development and thousands of generations more recent in ancestral history than the mass of the others.

Conspicuous among these are the uterus and mammary glands of the female and the lungs in both sexes. The rudiments of a stomach appear in the amœba, of a muscle-nerve apparatus in the hydra, and of a heart in the mollusc: but the whole invertebrate world with its myriad forms of life is traversed, and three or four of the widest strata of the vertebrate before the air-breathing lung appears in the amphibia. And the same order is followed in the embryo, even the gill-clefts, bars, and arteries putting in their appearance first as if to emphasize the thought what a mere parvenu the lung-sac is. The case of the uterus and milk-gland is even more marked, for the methods of parturition are such as to render both of them unnecessary right up to the very latest and smallest class of even the vertebrates, the mammalia. And by a singular coincidence all three of these organs are peculiarly subject to disease, and to a degree for which no adequate explanation has yet been advanced. Diseases of the lung, for instance, are responsible for one-fourth of the entire death-rate, more than double the proportion which can be attributed to any other single organ or even system, while the uterus and mammæ are the site of nearly 60 per cent. of all cases of cancer in the female.

In the case of the lungs, part of this extraordinary susceptibility may unquestionably be explained by the strain to which they are subjected by the sudden and frequent changes in their special environment—the atmosphere; but this can account for only a minor part, as some 65 per cent. of the lung death-rate (45 per cent. of the entire rate) is due to a single specific process—tuberculosis—which can hardly be attributed to exposure. The same is true of the uterus and mammæ, the overwhelming mass of whose fatality is caused by a special disease, carcinoma, in whose causation neither functional strain nor traumatic injury can play more than the slenderest part, popular and even professional superstition to the contrary notwithstanding.

Would not this peculiar morbidity of all three of these organs be best explained upon the principle of the general law already referred to, that late ap-

pearance means early decay, and that morphologic and ancestral weakness is usually accompanied or followed by premature functional senility? This, I think, can be almost demonstrated in the case of the uterus and mammæ, the vast majority of whose peculiar diseases develop only after their functional activity has ceased and they have become practically supernumerary organs, waste tissue in the body, which, like "dirt" elsewhere, is sure to breed disease.

ECHOES AND NEWS.

VON BRUNN, professor of anatomy in the University of Rostock, is dead.

THE *Lancet* has despatched a special correspondent to the seat of war in West Africa.

THE TWELFTH INTERNATIONAL MEDICAL CONGRESS will be held at Moscow from June 7 to 14, 1897.

THE ALBERTO-LEVY PRIZE of 50,000 francs has been awarded by the Paris Academy of Sciences to Professors Roux and Behring in equal parts.

DR. JOHN D. ROSS, of Williamsburg, Blair County, Pa., has just completed the sixtieth year of a continuous subscription to the *American Journal of the Medical Sciences* and to THE MEDICAL NEWS since its first issue. He is now in his ninetieth year, and still takes an active interest in medicine.

LUDWIG TEISCHMANN, formerly professor of anatomy at the University of Cracow, died recently at the age of seventy-three years. His name was generally known in association with hemin-crystals, of which he was the discoverer, and which have such profound significance in medical jurisprudence.

THE CHAMBER OF COMMERCE has been occupying itself with a study of light and air with the intent to restrict the skyward aspiration of buildings. In Berlin the height of buildings is limited to the width of the street; in Paris to about 50 per cent. over such width; in Chicago to 130 feet, and in Boston to two and a half times the width of the street.

THE explanation for the increase in the New York tax-rate, given by the Governor, shows that it was largely due to increased expenditures for new charitable purposes, including a very considerable item for the "new institutions ordered by the Legislature."

Perhaps if we would put some of the money that now goes into "homes" and asylums into school-houses we might have fewer paupers and lunatics to support.

IF it were the custom to erect a monument to a man in his lifetime for services to humanity, Dr. Hafikine of all men deserves one. After inoculating forty thousand persons for cholera in India at considerable personal expense he is returning to Europe shattered in health. It is doubtful if he will ever be able to expel from his system the Assam malaria which brought his noble experiments to a close. His inoculations reduced the death-rate materially.

ON the 15th of July last Dr. S. Moos, of Heidelberg, one of the founders and editors of the *Archives of Otology*, died on his sixty-fourth birthday. Rising from an obscure parentage, and battling with the most adverse circumstances and many difficulties, his heroic courage overcame all, and enabled him to write his name among the foremost scientists of his age. His writings have greatly enriched the literature of his specialty. In recognition of his merits his sovereign bestowed upon him the honorable title of counsellor.

THE recent election at the New York Academy of Medicine resulted in the election of Egbert H. Grandin, Vice-President; Joseph E. Janvrin, Trustee; Herman L. Collyer, member of Committee on Library, to serve four years; B. Farquhar Curtis, member of Committee on Library, to serve five years; Robert A. Murray, member of Committee on Admissions; William S. Gottheil, Reginald H. Sayre, Ralph L. Parsons, and Charles H. Richardson delegates to the Medical Society of the State of New York.

FROM the returns of the last census from the city of Paris, compiled by Dr. Bertillon, it appears that there are 2922 medical men residing in the capital, and of this number 521, or upward of one-sixth, are foreigners. The total number of foreigners living in Paris being 181,000, there are, consequently, 2.87, or in round figures 3, foreign physicians to 1000 foreigners, whereas there is only 1 (exactly 1.07) French physician to 1000 French inhabitants.

An examination of the table of professions shows that the practice of medicine attracts to the capital of France more foreigners than any other profession.

THE NEXT MEETING OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA has been appointed at Harrisburg, Pa., beginning Tuesday, May 19, 1896, and continuing for three days. The Committee on Scientific Business have issued a circular requesting that all papers offered shall be so condensed that they may be read in ten minutes, and that each discussion shall be limited to five minutes. The programme will be arranged as usual in the order in which applications may be received. The titles should be furnished the Chairman of this Committee as soon as possible, and not later than March 19th. The Chairman of the Committee is Dr. F. LeMoyne, Pittsburg, Pa., to whom all communications should be addressed.

THE Supreme Court of the German Empire has just pronounced sentence and ordered judgment in the following case: Dr. Max Böhm (Friedrichroda), a determined opponent of vaccination, some time ago was prosecuted for having certified to the successful vaccination by him of several children. The public prosecutor held that this vaccination was fictitious, inasmuch as a diluted lymph, incapable of conferring immunity, had been employed. The decision of the court at Gera, where the case was tried, was unfavorable to the defendant, but this judgment was reversed by the Supreme Court at Leipzig.

But the health authorities, instead of acquiescing in their defeat, again brought him up before the court at Gera on the same charge in May last. The court sentenced the defendant to two months' imprisonment. An appeal was again taken to the Supreme Court, but this time the judgment was sustained.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, January 2, 1896.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

INFANTILE INTUSSUSCEPTION. A STUDY OF 103 CASES TREATED EITHER BY ENEMATA OR LAPAROTOMY.

DR. FREDERICK HOLME WIGGIN read a paper with this title. He said that it was strange that at the close of the nineteenth century we should be still considering the comparative methods of treating intussusception which had been suggested many centuries ago—the method of intestinal distention by air or water and that of abdominal section. His attention had been first directed to this subject by a case of infantile intussusception coming under his own observation, and a search of the literature showed that this was very meagre in America and that it had received considerable attention in England. The importance of the subject was apparent when one considered that about 98 per cent. of the cases of infantile intussusception, if left to nature's care, terminate fatally.

At the outset one was met with the popular belief, shared by both physicians and the laity, that intestinal distention was a method which was both safe and, in many instances, successful, and that laparotomy in infants for the relief of this condition was uniformly fatal. If this opinion were founded in fact, of course there could be no choice of methods. To answer this grave question and to determine which method was the better, if each possessed certain real advantages, was the task which the author had set for himself, and he had begun his work by carefully collecting from English and American literature the histories of 103 cases of infantile intussusception. A study of these cases formed the basis of the present paper, but only a few illustrative cases were read, the remainder being intended solely for reference.

Dr. Williams has recorded in the *Lancet* for 1894 a case of intussusception occurring in an infant of eight months, seen on the first day of the trouble. After inversion combined with enemata and insufflation had failed to reduce the invagination, it was decided to try the effect of generating carbonic acid gas within the intestine. This was done by first giving an enema consisting of eight ounces of water in which was dissolved a drachm and a half of citric acid, and following this by an enema of eight ounces of a solution containing two drachms of bicarbonate of sodium. After holding the nates together for a few minutes, the tumor could no longer be felt, and the vomiting ceased. The patient made a good recovery. Among the cases unsuccessfully treated by enemata was one reported by Dr. F. Taylor and Mr. Golding-Bird. An intussusception of the ileocæcal variety was found in an infant of eight months, coming under observation on the first day. A tumor could be made out, and blood and mucus were passed by rectum. The tumor apparently disappeared after insufflation of air, but it returned some hours later, and then, under chloroform-narcosis, inflation was unsuccessfully tried again under increased pressure. The child died shortly afterward, and the necropsy showed that the invagination had not been reduced, but that an injection of water was capable of reducing the ileum, leaving the colon inverted. The latter proved to be gangrenous, and the injection at the necropsy caused several ruptures of the peritoneal and muscular coats.

Mr. Mortimer had reported in the *Lancet* for 1891 a case of intussusception occurring in an infant of eight months, coming under observation on the fourth day. The child was on the verge of collapse, but after stimulation two small enemata were given, and after the second one the tumor could not be felt. Opiates were given, and for two days there were some pain and increasing abdominal distention. The tumor then reappeared, and under chloroform, and with the reservoir raised three feet, several fluid enemata were given before the tumor partially disappeared. On each of the two following days a pint of water was injected at a lower pressure. The child died, and the necropsy showed three ruptures in the descending colon.

Dr. Edward Deansley recorded in the *Lancet* for 1894 a case of intussusception occurring in an infant of seven months, seen five days after the bowel had begun to protrude from the anus. Just prior to admission the symptoms had been aggravated by the mother giving castor oil. Under an anæsthetic an enema of one pint of water with an elevation of two feet was given, and this caused the disappearance of the tumor. The child was kept under opiates until the next day, and on the evening of that day the bowel again protruded and the vomiting returned. Reduction was again effected under chloroform, and also on the following day by the same method as at first. Twenty-four hours later the child died, and at the necropsy it was found that although the invagination was still unreduced, its reduction could have been easily effected by laparotomy.

In a case of intussusception occurring in an infant of three months, and reported by Mr. J. D. Mortimer, it was supposed that reduction had been produced by insufflation, but some hours later the child died in collapse, and the necropsy showed the invagination still present. It was then ascertained that with an enema under a water-pressure of two feet all of the invagination could be reduced except about one inch of the ileum, together with the cæcum and appendix. Only a little more reduction was produced by increasing the pressure to three or four feet, and in a few minutes the colon ruptured in three places. It was worthy of note, however, that the invagination was very readily reduced by manipulation from below. The reader of the paper then referred to some experiments of Mr. Mole on infantile cadavers, and quoted his conclusions from these experiments as follows: (1) That no harm can be done healthy intestine by enemata of fluids under a moderate pressure; (2) that hydrostatic pressure is more uniform, and, therefore, less likely to cause rupture of the bowel; and (3) that the part most likely to be injured by overdistention is the transverse colon.

Out of the 103 cases of infantile intussusception presented in this paper nearly 50 per cent. occurred during the fourth, fifth, and sixth months in nearly equal proportions; 75.4 per cent. were in males, and 89 per cent. were ileocæcal. The probable causal relation of external violence was then referred to, and Pritchard and A. Jacobi quoted in support of this view. It seemed prob-

able that the careless handling of infants and particularly the violent jumping of the little ones up and down to quiet their crying were responsible for many cases of intussusception.

As regards the symptomatology of the cases collected, nothing especially noteworthy had been observed. The disorder had manifested itself by sudden and severe abdominal pain, vomiting, bloody stools, and, in most cases, by the presence of an abdominal tumor. It should be noted that the presence of this tumor would have been overlooked in some instances had not conjoined abdominal and rectal palpation been employed. A protruding tumor at the anus was noted in 5 per cent. of the cases. A spontaneous cure by sloughing was observed in only 2 of the cases. Of the 39 cases treated only by inflation or enemata, or both, 16 recovered, giving a mortality of 59 per cent. In the 16 successful cases various methods were employed. In one case 9 enemata were necessary to reduce the invagination permanently; in 3 chloroform-narcosis was employed. The average hour at which treatment was begun was the forty-first, whereas in the 23 unsuccessful cases the average hour was the sixty-ninth. In reality, 72 cases were treated by intestinal distention, but some of these were afterward subjected to laparotomy. Of the 72 cases reduction was not secured in 54, or 75 per cent., and this represents the mortality of this method of treatment had not other means been subsequently employed.

Various experimenters, the speaker said, had shown that there was little risk of injuring a healthy infantile intestine by injecting fluid under a hydrostatic pressure of six pounds to the square inch, but when the gut is constricted the conditions are very different, even when the disorder has lasted only a few hours. Battey and Mole have proved by experiment that water under moderate pressure can be made to pass the ileocæcal valve when no obstruction is present, and Mole has shown that if 1½ pints of water are injected under a pressure of 1⅓ pounds to the square inch into an infantile colon, the intestine will be fully distended and the fluid will pass the valve. The author said that while he could not bring himself to favor treatment of infantile intussusception by enemata or inflation after having studied this series of cases, still, if one desired to resort to intestinal distention, at least 1½ pints of tepid saline solution should be placed in a reservoir elevated not more than three feet, and injected into the bowel. If one trial of this method did not reduce the invagination, the method should be at once abandoned. If reduction has apparently taken place, the child should be kept quiet by other means than opiates or motion, for the opiates tend to mask the symptoms indicative of a return of the invagination. The author then quoted the expressed views of a number of well-known surgeons to emphasize still further what the cases presented in the paper taught, viz., that intestinal distention was uncertain, unreliable, and dangerous.

Turning next to a consideration of the cases treated by laparotomy, it was shown that of the 64 cases so treated 43 had terminated fatally, thus giving a mortality of 67.2 per cent. In the successful cases the average age of the patients was 6½ months; in the fatal cases it was 5 months. In the successful cases the operation had been done on an average at the forty-fourth hour from the onset of the acute trouble; in the fatal ones, the operation had not been done until the one hundred and second hour. If the cases in which the bowel was incised or excised were excluded, there would remain 45 cases, 24 of which were fatal. This would reduce the mortality to 53.4 per cent; but even this the author did not consider represented the risk from this treatment at the present time, owing to improvements in the technique of intestinal surgery. On this account he would exclude all cases occurring prior to 1890, which would leave 18 cases of infantile intussusception treated by laparotomy, with 4 deaths, or a mortality of 22.2 per cent.

As regards the treatment itself, he said that it was foolish to operate on a child in collapse; it should first be stimulated until reaction had set in. Only a very short incision was necessary. The best method of reducing the invagination was by encircling the tumor below its apex by the finger and thumb, while the intussuscipiens or sheath is held a few inches lower down, and the apex of the tumor pushed upward without making any traction from above the tumor. If it should happen in the future that after doing a laparotomy it was found that the invagination was irreducible, the best method of meeting this formidable complication, in his opinion, was by the method devised by the late Prof. H. Widenham Maunsell. It should be remembered that acute intussusception was really a form of strangulated hernia; that the subacute variety was like an irreducible hernia; and that by laparotomy performed within the first forty-eight hours 78 per cent. of the cases should recover.

DR. A. JACOBI said that the reported cases were exceedingly few in proportion to the number of cases that must have occurred. Invagination of the intestine was more apt to occur in infants than in older subjects, both on account of the looser attachment of the mesentery and the greater exposure of this region of the body to external violence. He considered the condition largely a preventable one. Thus many of these children, it would be found, had suffered for a long time previously from constipation or diarrhœa. In the former case, the straining incident to having a stool was, in all probability, an exciting cause of intussusception under certain circumstances; while in the case of protracted diarrhœa, the deeper tissues of the bowel becoming involved in the disease-process, localized peritonitis and spots of thickening are produced. Regarding treatment, the speaker expressed his belief that if enemata, correctly employed, failed to effect reduction in the course of a few hours, a surgeon should be summoned. He had come to the conclusion that it was not only safer, but better, not to employ a greater water-pressure than one to one and a half feet. With such moderate pressure a larger quantity of fluid could be introduced into the intestine. He had always been in the habit of prescribing opiates for children immediately after reduction of the invagination had been effected, in order to keep them quiet. In one reported case in which the invagination recurred many times, he was of the opinion that this might have been prevented by the use of opiates.

DR. B. FARQUHAR CURTIS said that in 1887 he had collected some statistics regarding intussusception, which showed that in the case of both infants and adults the mortality was 76 per cent. Additional and more recent statistics had reduced this rate to 58 per cent. He

thought we would be doing very well if we saved one child in two or three. He did not think there had been such a change in the technique of the operation in the last few years to account for this reduction in the mortality; it was more probably due to an earlier resort to operation. It was well to remember that this was a class of cases in which it was eminently wise to call in the surgeon at an early stage, for counsel if not for operation. Where there was an acute onset, the operation should not be delayed. It was hardly fair to convey the impression that laparotomy was not followed by a recurrence of the invagination—that this was only seen after intestinal distention—for a number of such cases of recurrence have been recorded as following laparotomy. An enema, in his opinion, should be tried only once in these cases of infantile intussusception, and should be administered under an anæsthetic, and with a "head" not exceeding three feet. Where laparotomy was indicated, it should be performed very quickly, through a very short incision, and the reduction of the invagination effected within the abdomen.

DR. J. LEWIS SMITH said that in differentiating between the stools of dysentery and those of intussusception it should be remembered that after the first few hours all fecal matter was absent from the stools in cases of intussusception. He had successfully employed both inflation and fluid enemata in the treatment of infantile intussusception, but had been convinced of the greater efficacy of the latter. In his experience there had not been a previous history of chronic diarrhœa in cases of intussusception occurring in infants between six months and one year old.

DR. R. VAN SANTVOORD said that as some believed that infantile colic was really a form of mild and transitory intussusception, the importance of promptly treating this condition, and by the careful use of opiates or other measures controlling the movements of the bowel, became manifest.

DR. WIGGIN, in closing the discussion, said that he had objected to the use of opium in these cases chiefly on account of it masking the early symptoms indicating that there had been a return of the invagination. He would again emphasize and contrast the time at which the successful and unsuccessful cases treated by intestinal distention had come under observation, as indicating the great danger of delay. The same observation applied with equal force to the laparotomy-cases reported. A very short incision was all that was necessary. He did not think that in infants laparotomy had often been followed by a recurrence.

THE LOUISVILLE CLINICAL SOCIETY.

BY W. H. WATHEN, M.D., LL.D.

OVARIAN CYSTOMA.

CASE I.—A year ago a doctor consulted me about a woman who had an abdominal enlargement which he had diagnosticated an ovarian tumor, but the history was peculiar, in that she claimed the tumor had several times nearly disappeared. Six months ago she came to the city to see me, and I diagnosticated an ovarian cystoma, and recommended an operation. She repeated to me the history of the case, claiming that the tumor had almost entirely disappeared upon several occasions, and now claims that it has nearly disappeared once since she consulted me.

I operated ten days ago and found a multilocular ovarian cystoma, containing more than three gallons of liquid in all the loculi, with extensive adhesions to the anterior abdominal wall. The only interesting feature in the case is that this is a positive illustration of the fact that we cannot rely upon the statement of our patients in regard to the progress of any form of tumor, because we all know that this tumor could never have disappeared or have become lessened, and it was only in the imagination of the patient that it did so. I have had one case where a large tumor did disappear and return, but that was a parovarian cyst, unilocular, with thin walls, which evidently ruptured; the contents being bland, were absorbed into the system and eliminated through the excretory organs. The tumor returned afterward, and fifteen years subsequent to the rupture was removed by me, and weighed fifty pounds.

INTRALIGAMENTOUS MYOMA.

CASE II.—The second specimen is a uterine myoma, removed two weeks ago from a lady who had noticed the presence of a tumor for two or three years, and for a year had suffered with intense pain from its presence. Examination revealed the fact that the tumor was firmly fixed in the pelvis, almost immovably so; the diagnosis of intraligamentous or retroperitoneal myoma was made. Believing that the tumor might be removed by the vagina by morcellation, though the vagina was very small, the woman never having given birth to a child, the vagina was prepared for a vaginal hysterectomy, and at the same time the abdomen for an abdominal hysterectomy. After the woman was under the anæsthetic an examination convinced me that it would be unwise to try to remove the tumor through the vagina, and that it would be best to deal with it from above; but, as the uterine arteries could be ligated without difficulty from below, I ligated both arteries through the vagina. I then opened the abdomen and found that the tumor was so firmly wedged into the pelvis that it could not with strong vulsellum forceps be carried up more than half an inch. The tumor, which has shrunken since being put in alcohol, was large enough to fill the pelvis to the walls upon each side, and was an intraligamentous myoma arising from the lower and anterior part of the body of the uterus at its junction with the cervix. There were no broad ligaments, properly speaking, but the ovaries and tubes were well above upon each side, so that I was able to throw a ligature around the ovarian arteries. Then an incision was made around the entire mass, about one and one-half inches from the top of the tumor, and the tumor and uterus enucleated, the uterus being divided at its junction with the cervix. When the enucleation was completed there was a large cup-shaped cavity extending down to the vagina, and outward to the pelvic wall. The capsule was preserved, and the best way to treat the case was manifestly after the fashion of Senn, which consists in stitching the capsule in the lower part of the abdominal incision, then tamponing it with iodoform-gauze. This was done and the wound closed. The woman was very nervous, with a bad heart; her pulse was exceedingly rapid during the operation, and remained from 120 to 160 for five days, not from shock of the operation, but from the generally enfeebled con-

dition of her system. She has improved continuously, and is now sitting up.

SUSPENSIO-UTERI BY VENTRAL FIXATION.

CASE III.—The next specimens were removed from two women; operation practically the same in each case, but not for exactly the same purpose. A lady from Galesburg, Ill., single, aged twenty-five years, consulted me last fall for the purpose of getting me to remove her uterus, she having been under the treatment of many doctors and deriving no benefit. She had become almost a confirmed invalid, suffering intensely during her menstrual periods, but never free from pain, and practically unable to do anything. I found she had a high fever, which could not result from her pelvic trouble, and sent her home. The case proved to be one of typhoid fever, and she finally recovered. She returned to the city recently, and upon examination I found her uterus completely retroflexed and wedged down in the pelvis, with tenderness in the ovarian and tubal regions, and some enlargement. I operated upon her through the abdomen, bringing the uterus, tubes, and ovaries from their retroplaced position, and found the normal structure of both ovaries entirely destroyed. Both ovaries and tubes were removed and the uterus fixed to the abdominal wall by silk sutures upon each side, which united each cornu of the uterus to the peritoneum, the knotted ends of the sutures being buried in subperitoneal fat. Then another suture was introduced through the abdominal walls and the fundus of the uterus and tied externally. The peritoneum was scarified so that adhesion would be more perfect. The woman has had none of her nervous trouble since, and the uterus is firmly fixed.

CASE IV.—The other specimens were removed from a woman in this city. She also had a retroflexed uterus which could not be returned to its normal position and held there by a pessary, as I had tested this method for a long while. The ovarian and tubal regions were exceedingly tender; she suffered from dysmenorrhœa, and there was always pain in the pelvic region. I could detect no enlargement of the ovaries or tubes. In fact, the pain she suffered, while it was severe and while she insisted upon an operation, was not sufficient in itself alone to demand the operation; but she had for many years suffered from a facial eruption which at times disfigured her so much that she had felt unless she could be cured she would rather die than live. And she believed that the continuance of the eruption was largely due to the trouble with her womb or with her ovaries and tubes, and that the eruption was worse during her periods of pain, etc. After having talked about the operation for two years she, with the approval of her mother, determined that it should be performed, and I consented to do so. This patient had been treated by several of our best skin specialists in the city, including Drs. Bloom, Orendorf, and others. She had also consulted Dr. Mathews concerning some rectal trouble. I operated upon her after the same fashion as in the previous case, removing both ovaries and tubes, which were found to be not so badly diseased as in the other case, but considerably diseased—enough so to cause intense pain during menstruation and more or less pain at all times. She has made a good recovery; the eruption is decidedly better. What will be the permanent result of course the future will have to decide. The operation was performed three weeks ago. I must say that the operation was performed more with the hope of benefiting the eruption than for the purpose of curing her of pain, though the pain was severe.

FIBRO-SARCOMA OF VAGINAL WALL.

CASE V.—About six months ago Dr. Weidner called me in consultation to see a woman pregnant in about eight months. There was a tumor in the left vaginal wall just below the uterus about as large as a turkey's egg. We did nothing, and the woman gave birth to the child, as I understand, without serious trouble. The tumor remained, not enlarging appreciably. Some weeks ago she insisted upon having it removed, and Dr. Weidner referred her to me. She was taken to the Kentucky School of Medicine Hospital and we removed the tumor by dividing the vaginal wall and enucleating it. The tumor had the appearance of being a fibroid. Dr. Weidner has since examined the specimen and pronounces it a fibro-sarcoma, and reports that he thinks there is a recurrence of the trouble. This specimen is interesting in view of the fact that we have very few solid tumors connected with the vagina, and especially few malignant tumors, unless they be carcinomata, extending to the vagina from the uterus or the vulva.

DISCUSSION.

DR. J. M. MATHEWS: I wish only to refer to the fourth case Dr. Wathen has spoken of. If the members were as familiar with the case as I am, I know they would all regard it as an extremely interesting one. As far back as six years ago the young lady was referred to me with the most violent eczema of the face that I have ever seen, and in her own good way—she is much above the average in intelligence and is connected with a very nice family—she said she believed that the eczema was due to her rectum; that she had difficulty in having an action of the bowels; that she was thoroughly constipated; had to strain at stool, etc., but great stress was put upon the violent eczema of the face. This was distressing, much more so than Dr. Wathen has mentioned. At night the itching was so intense that she would scratch the blood out of her face; she could not sleep, and being a young girl she was diffident about going into society, because, as Dr. Wathen has stated, of the terrible appearance that she presented. But she told me she could put up with that were it not for the torment she passed through, especially at night. To give her some relief, thinking perhaps it might be due to neurotic influences, that she might be correct in thinking the rectum had something to do with it, I chloroformed her and divulsed the sphincter muscle, hoping by that method to relieve some reflex process and to re-establish normal action of the bowel, etc., but signally failed. She consulted me on several occasions for prescriptions for her constipation, etc., but in the interim I referred her to Dr. Bloom, who treated her how long I do not know. I saw her during the whole time up to perhaps a year ago semi-occasionally, being interested in the patient obtaining permanent relief if possible. She consulted many physicians, not only here but abroad, in New York, etc., going through various forms of treatment without much benefit. I

always believed it was neurotic; where the source of irritation was I, of course, am unable to say. Happening in the St. Joseph Infirmary operating-room recently a patient was wheeled in by Dr. Wathen's assistants, and I recognized this girl. I was so much impressed, not knowing that she was going to have a laparotomy performed, or that she had any trouble with the abdomen, by the kindness of Dr. Wathen I witnessed the operation, and went so far as to say to him that I hoped he would find disease of the ovaries or tubes, the removal of which would result in benefit, as she had been in torment for years. I stepped into her room this afternoon; she has made a perfect recovery from the operation, and told me that her face had given her no trouble since the operation was performed, three weeks ago. If it does succeed in clearing up this terrible eczema, it will open a subject for discussion. It has been the most persistent case that I have ever seen, and I only hope that the operation may prove of benefit.

DR. CARL WEIDNER: I will only speak concerning the last case reported by Dr. Wathen—the growth removed from the vaginal wall. Upon examination the specimen proved to be a sarcoma of rather large cell, being of the spindle-cell variety. The reason I think there is going to be a recurrence of the trouble is because I have examined the patient and find a rather swollen, tender condition, and some irregular excrescences about the line of the incision; second, the nature of the trouble; third, the continued debilitated state of the woman. She has not regained strength, and is suffering more or less pain locally and in the back. The case has been interesting, if for no other reason than the facility with which delivery was accomplished, considering the presence of the growth in the vagina at the time. I anticipated considerable trouble during labor, and this is one reason why I called Dr. Wathen to see the case. I waited for the occurrence with a great deal of anxiety, and after repeated failures was summoned hurriedly one day, and when I reached the house the child was born, the mother having had comparatively little trouble. However, it was a very small child.

DR. P. GUNTERMANN asked why Dr. Wathen removed the ovaries and tubes in two cases reported, stitching the uterus to the abdominal walls, when disease of the uterus had been diagnosticated. He understood the doctor to say it was a very simple matter to take out the uterus either from below or above, but in this case he had removed the ovaries and tubes and left the diseased uterus stitched to the abdominal wall.

DR. LOUIS FRANK: The second case Dr. Wathen reports is to me the most interesting in the series. This tumor seems to spring from the upper portion of the uterus. Tumors springing from the lower lateral part of the uterus, as a rule, burrow between the broad ligaments retroperitoneally, and those springing from the upper portion of the uterus grow outward in the direction of least resistance. This tumor must have begun at least between the folds of the ligament, probably just below where the tube enters the uterus.

As to the method of treating wound-cavities after removal of this sort of tumor of the uterus, I think by stitching up the sac which we have left, as has been recommended by some authorities, the denuded surface draining through the vagina, as could very readily have been done in this case, we secure the most rapid convalescence. It might also have been advisable to remove the remainder of the cervix, as the uterine arteries had already been ligated. Whether this would have simplified the after-treatment of the case I do not know. I would like to ask Dr. Wathen, in closing the discussion, to state whether there was much hemorrhage during the operation. If not, then the rapid pulse might be accounted for by the fact that we frequently have, if a fibroid tumor has existed for a great length of time, fatty degeneration of the heart. This, in connection with the operative procedure, and the shock which we know results to the nervous system, would probably account for the rapidity of the pulse subsequent to the operation.

In the next case reported, the connection between the ovarian disease and skin-lesion is an interesting one. It would be interesting to know the exact condition which existed in the ovaries. I rather question, however, though I confess I know little concerning skin-diseases, that there could be any connection whatsoever between ovarian disease, or disease anywhere, and eczema. We know that eczema sometimes persists for years. I have seen cases of facial eczema persist for such a length of time that the face assumed an appearance simulating leprosy—the so-called *facies leonis*—from the extreme induration and thickening of the skin.

DR. I. N. BLOOM: Referring to the fourth case reported by Dr. Wathen: Ten years ago this month a young lady came to me suffering from a very severe eczema of the face, also with acne; the two at times appeared together. When the eczema was most marked the acne was less so, and *vice versa*. During the four months that she was under my care, at times she improved to such an extent that I thought her ultimate recovery was assured; but an exacerbation would occur. The young lady became considerably discouraged; and at the end of four months, as she was not cured, decided to try someone else, and applied to my friend, Dr. McGuire, who reported, at the end of a months' treatment, that she was wonderfully improved; then she had another exacerbation. She continued under Dr. McGuire's treatment, however, until he left the city. It seems that some time afterward she applied to Dr. Mathews for treatment, as he has stated, with no better results, as far as the eczema was concerned. She then seems to have passed into the hands of Dr. Wathen, who is the first operator in the world, I believe, to perform a laparotomy for the cure of eczema. If he is successful, he will have established a new method for curing one of the most persistent and obstinate diseases that we are called upon to treat. The time (three weeks) is rather short. It is not at all surprising that, after having had a laparotomy performed upon her, the patient should not complain of itching of the face; but three weeks is too short a time to demonstrate the cure of eczema. Four months would be considered a short time in which to effect a cure of the disease when as long standing as in this case—ten years. At the time this patient was under my care she had absolutely no symptoms referable to disease of the sexual organs. I took occasion to make careful inquiry into her history, and studied every feature very thoroughly. I remember the case as distinctly as if it had occurred but yesterday—more distinctly, in fact, because I utterly failed to cure the eczema; and, as I have stated, at that time there were

no symptoms referable to the reproductive organs. I propose to ask the doctor why he thinks the operation that has been performed will effect a cure of the eczema. I would like to have had him dwell a little longer upon the disease of the ovaries which he found. Dr. Mathews spoke particularly of the disease of one ovary, and the reporter mentioned that the ovaries *were diseased*, but less so than the preceding case, with a similar condition of the uterus. I would like to ask the doctor whether the disease of the ovaries, when brought to view, was sufficient to call for their removal, or whether the retroflexion of the uterus was sufficient to demand an operation as severe as the one he performed. The case is an interesting one, but is not entirely unique.

I regret to say that I have under my care at the present time a young lady with an exactly similar condition of affairs. I have been treating her six months, and the course of treatment has been the same as employed ten years ago in the case Dr. Wathen has reported. Had I known that Dr. Wathen was to operate upon the case I would have brought a letter received two or three days ago, which would serve to illustrate a few points. The young lady that I am now treating has exactly the same condition of affairs; she is a robust, healthy girl; good surroundings, fairly well educated. She has a severe facial eczema accompanied by intense itching. Improvement at times has been marked, and encouraged by that she has continued treatment, although there have been periods of exacerbation when the case would appear altogether hopeless. Her last letter, received yesterday, states that she is greatly improved, and asks whether she shall come to see me at her regular time. This young lady, accompanied by her brother, has visited me once each month for six or eight months. I have inquired into her history thoroughly, and there is absolutely no symptom referable to the uterus or any other organ. The stomach and intestines are most frequently affected in these cases, not the sexual organs. She says if her face were well she would be as healthy as it is possible for anyone to be. In another case exactly similar to the two preceding, in which I am glad to say I had a more fortunate termination, the trouble had existed for a great many years and was thought by some who had seen it to be leprosy. In referring the case to me Dr. Dugan sent me a few hastily written lines, at the end of which he asked, "Is this leprosy?" A complete cure resulted under three months' treatment, the case being one of simple eczema.

DR. J. M. MATHEWS: I would like to ask Dr. Bloom if the neurotic element plays any part in the development of eczema.

DR. I. N. BLOOM: I do not know what is meant by the neurotic element. If you mean the reflexes, I should say it is extremely rare, and I doubt if it ever has any great influence.

DR. J. M. MATHEWS: In other words, suppose there is a tendency on the part of a patient to eczema, perhaps very slight—is it not a fact that the neurotic element will so increase that disease as to make it permanent? If there is disease, be it eczema or whatever you may choose to call it, and there is a local source of irritation, I do not care where it is, in the bowels, in the uterus, or in the ovaries, is it not true if you have a local seat of irritation, that this, through the neurotic tendency, will increase the eczema to such a degree as to make it a persistent affection so long as you have the local source of irritation?

DR. I. N. BLOOM: Anything that diminishes the vitality of a person, such as diseases of any kind, would naturally tend to delay the cure of eczema; but I maintain that it is not through any neurotic element, but simply an impaired vitality. Consequently, if stomach-trouble of a chronic nature developed during the course of an eczema or previous to it, the eczema would probably be rendered worse thereby. If I were treating such a patient, I would endeavor to cure the stomach-trouble as quickly as possible, just as I would cure acne or any other disease where it was coincident with eczema; at the same time I would say that one is entirely independent of the other. Eczema perhaps more frequently than otherwise affects strong, robust, healthy persons, which would be a point against the influence of any form of reflex action.

DR. W. H. WATHEN: Dr. Bloom, in his answer to Dr. Mathews' inquiry, has stated the main reasons why I consented to remove the ovaries in the fourth case I reported. Here was a woman who believed for a long while, so she reports, that the eczema has been made worse and continued largely because of her menstrual functions being interfered with, and the pain which she has suffered.[1] This woman has had since I have known her imperfect nutrition, and I am reasonably sure from a rather extended experience in operating for the removal of ovaries that her general nutrition will be very much improved.

Knowing that to be true, then, from Dr. Bloom's own statement, her local condition upon the face would be more amenable to the ordinary treatment for eczema. The case has positively shown that it has resisted the efforts of all the dermatologists who have treated her, and that the condition is not amenable to the treatment they have pursued, unless something be done to improve her nutrition. The operation for removal of the ovaries was not performed for the purpose of curing the eczema, nor was she promised that she would be benefited, but was discouraged against having the ovaries removed at all; and was finally only told that it might benefit her by improving her general nutrition. But this woman had enough disease about the pelvis to justify a laparotomy independent of eczema; and the operation of laparotomy and anterior fixation of the uterus, where it is retroplaced and cannot be returned and held in position by a pessary, is one that is so well recognized that no intelligent laparotomist would take issue at all. In this case, then, the operation was justifiable for the purpose of fastening the uterus to the abdominal wall, and I did not know when I began operating that I would remove the ovaries, thinking that probably much or most of the pelvic irritation and painful menstruation was due to the retroplaced uterus, but when the ovaries were exposed, and one of them found considerably diseased and the other not healthy, as she had insisted upon the removal of the ovaries, and when Dr. Mathews, who was present, insisted that they ought to be removed, because she would never want to marry, they were removed. I do not know with what this woman suffered ten years ago, because I had no opportunity of ascertaining.

[1] If that be true, then the removal of these structures ought to act beneficially upon the condition with which she has suffered.

ORIGINAL ARTICLES.

THE DIAGNOSIS OF CHANGES IN THE SIZE, POSITION, AND MOTILITY OF THE STOMACH IN CASES WHERE INTRAGASTRIC INSTRUMENTS CANNOT BE USED.

BY BOARDMAN REED, M.D.,
OF ATLANTIC CITY, N. J.

IT was only twenty years ago, in 1875, that Ewald[1] by accident discovered that a soft, flexible tube could be introduced into the stomach without a stylet. Since then the use of this instrument has been very widely extended. When in 1885 the writer took his first lessons in lavage under Oser, in Vienna, it seemed almost a novelty there, and was very rarely employed in the United States; but it has been more and more popularized, until now in some quarters it has possibly come to be abused, especially by patients who have learned to wash out their own stomachs.

There are many cases of gastric disease in which, for one reason or another, we cannot employ even the soft tube, and still less the sound, or any of its ingenious modifications and amplifications, such as Einhorn's gastrodiaphane or Turck's gyromele. The contraindications are given by the leading authorities, and include especially all cases of acute illness, recent hemorrhages from any part, gastric ulcer as a rule, most serious diseases in their last stages, congestion of the brain, and advanced age. It needs to be remembered, however, that age for this purpose should be reckoned by the condition of the heart and bloodvessels, rather than by years. I have had patients eighty years of age who took the tube with less inconvenience than many do at forty.

Then, besides the contraindications, we are obliged to take into account the foolish dread which many nervous patients have of this trifling procedure, amounting sometimes to an insuperable obstacle. In my long experience with chronic invalids in Atlantic City, the most frequented health-resort in America, I have found that only a small proportion of patients of the better class who need special treatment will consent to the use of a stomach-tube, at least until their diseases have progressed to a serious stage.

Therefore, in order to reach as accurate a diagnosis as possible in such cases, I have been obliged to make the most of the various methods which do not include the employment of any instrument inside the stomach. Trusting that the mode of systematizing such methods which has proved useful in my own work may be helpful to others, I venture to submit a description of it.

In thus pointing out what can be done when necessary without the tube, there is no thought of underestimating the enormous advantages which that little instrument affords in the diagnosis and treatment of gastric disease. In studying the chemical functions of the stomach the tube is virtually indispensable, though occasionally accidental vomiting at the right time gives an opportunity for making the necessary chemical tests; and the Einhorn bucket may sometimes serve us a good turn.

It would require too much space to go into a discussion of symptomatology and the now somewhat promising results of the chemical and microscopical examination of the urine and blood. That these latter researches are capable of throwing much light upon the affections of the stomach as well as of those of the intestines there is no longer any question.

We come then at once to the examination of the abdomen externally. Not stopping here to consider what can be learned from inspection and palpation, as to the usefulness and great value of which no question has ever been raised, we pass on to a study of clapotement and percussion. It is to the value of the combined employment of these two procedures, according to a certain order, that I desire to call attention especially. Both are separately well described in the works of Ewald,[2] Boas,[3] and other standard treatises on diseases of the stomach, and during recent years there have been numerous contributions to current medical literature on abdominal percussion. The most notable of these is a paper by Dehio,[4] in which he gives directions for percussing with the patient lying on the back, as well as standing, after drinking various portions of water. He states that the normal empty stomach is entirely within the thorax, and not accessible to percussion, but that the drinking of one-quarter of a litre of water produces in the erect position a dull area, which extends 11½ cm. below the lower end of the corpus sterni; then by drinking the same quantity a second time, the dulness is extended 2.7 cm. further downward, and so on until after the person has taken a whole litre he finds in the ma-

jority of cases the lower border of stomach-dulness a few centimetres above the level of the umbilicus. He points out also that from the different degrees of distensibility thus indicated we may infer much as to the motility of the stomach.

On the other hand, Jaschtschenko,[5] at about the same time, took quite the opposite view of the matter. He sharply criticises Traube, whose conclusions were similar to those of Dehio above cited, and declares that the empty stomach is percussible, and that filling it gradually with water causes an extension of the dulness upward but not downward. Neither of these two writers makes any mention of clapotement.

Obrastrow,[6] of Kiel, writing on this subject in 1888 an elaborate and valuable paper which I had not seen till the present article had been nearly finished, gave a full exposition of clapotement, but had not at that time as much faith in the accuracy of the information to be obtained by a delicate percussion as he has evidently since acquired, judging by an able contribution which has just appeared from his pen.[7]

Rose,[8] an American physician, has also recently written on the subject of the splash.

Certain it is that even the normally small healthy stomach under usual conditions, when empty as well as full, presents a portion of its anterior surface in contact with the front wall of the thorax, and to a small extent with the front wall of the abdomen; and except in conditions of marked obesity it is not generally very difficult to determine both the upper and lower borders of that portion in contact. But stomachs which are thus almost entirely covered by the ribs are rare, at least in civilized communities, and physicians are seldom called upon to prescribe for them.

Physicians are most interested in abnormal stomachs, which nearly always extend far enough below the ribs to afford us the opportunity of testing their condition by all the usual methods of physical exploration.

My own experience has convinced me that stomachs, like noses, may vary considerably in size, and yet be within normal limits, but that when they extend, in the empty condition, much lower than a point midway between the sternum and umbilicus, they are generally pathological. That experience includes the examination of about 300 persons by the methods now under consideration. Two hundred and twenty-five of these were examined in the course of my practice in Atlantic City and the remainder in the Polyclinic of the Augusta Hospital in Berlin during the present winter, through the courtesy of Professor Ewald and his chief assistant, Dr. L. Kuttner. By the kindness also of Dr. Oesterreicher, pathologist at the same hospital, I have been permitted to witness numerous autopsies in the cases of persons who had had various forms of gastric disease as well as a few whose stomachs were normal as to their size and position.

At some future time I may summarize the results of these observations and of others yet to be made in a more general way, and deduce from them some of the lessons which they teach; but it is sufficient for the object of this article to show that they confirm the value of clapotement and percussion.

In a number of the cases in Ewald's clinic in which, by external examination, I had diagnosticated and designated by chalk-lines on the abdomen, gross departures from the normal in the way of displacement, dilatation, or both, the stomach was afterward inflated by air, and in some instances illuminated by the electric lamp from within, with a substantial verification of the results previously obtained. In two noteworthy instances while by percussion the boundaries were correctly determined, the splash obtained by clapotement told an entirely different story, and thus led at first to some doubt. But as exceptions are said to "prove the rule," so these two exceptional cases have been unusually instructive. Both were cases of downward displacement and dilatation. In one of them the entire stomach had fallen until the fundus rested firmly upon the pelvic organs; in the other the pyloric end, greatly dilated, occupied the same position, while the cardiac portion was still in its normal place. Percussion in various positions with the stomach first empty and afterward partly filled, gave the above results, and distending the organ with air was fully confirmatory; but the splash, even after one or two glasses of water had been drunk, could not be heard at any point below the navel in either case. Usually with the patient lying on the back the splash is heard at the nethermost part of the stomach when obtainable at all.

The practical inference to be drawn from this observation is, that if in any case clapotement and percussion do not agree in their testimony, we should be guided by the latter rather than the former, as being less likely to deceive, though until this recent experience I was inclined to the contrary view. When clapotement and the results of intelligent, careful percussion agree, we need have no doubt. When, as rarely happens, they disagree and the case is important, it will be well to inflate either the stomach or colon to settle the point. Experiments were made by me in a series of six cases of gastrectasia in Ewald's clinic with a view to ascertain whether by clapotement and percussion together it is possible to determine positively when the stomach has emptied itself. The patients reported in the morning fasting. In each of these cases when the splash was obtainable and percussion in the erect position demonstrated dulness in the

lower segment of the stomach, I was able afterward by means of the tube to bring up a considerable quantity of the undigested remnants of a previous meal. Then after carefully emptying the stomach by aspiration the former tests were again employed, and this time with negative results.

In a number of other (doubtful) cases that were required to present themselves in the morning fasting the presence of fluid in the stomach was suspected, and to determine the question I practised clapotement and percussion, but failed to obtain a splash, or to detect dulness over the lower part of the gastric area in the erect position. The tube was then used, but nothing obtained, except three or four grammes of a pale, thin solution, consisting mostly of saliva.

In this simple manner, therefore, we may test the motility of any given stomach frequently, at various intervals after various kinds of meals, with very little difficulty or inconvenience to the patient, especially after the boundaries have once been accurately determined.

Numerous experiments have also been made by me to determine whether the stomach fills upward or sinks lower after the taking of food or drink in successive portions. The results have been somewhat various, as might be expected, according to the muscular energy of the stomach tested. In the cases of gastrectasia and all cases of weak motility, there has been a depression of the lower border after each glass of water, except when it was already at the lowest point attainable, and then there was a demonstrable widening of the organ on either side. Since beginning this particular investigation I have unfortunately not been able to find many normal stomachs, but the few presumably healthy ones examined filled upward without the lower border as a rule showing any noticeable depression after drinking several successive glasses of water, thus confirming the observation of Jaschtschenko rather than those of Dehio and Taube. In some cases, however, in which there were no other signs of weakness, the area of dulness increased both upward and downward after drinking.

It is best to examine the patient at a time when the stomach should be entirely empty—that is, in the morning fasting or six hours at least after the last meal. But this is not always practicable, and after a light breakfast or a very moderate lunch a healthy stomach will usually be found by the tests of clapotement and percussion to have voided its contents into the intestine at the end of two hours. Even when these tests show that gastric digestion is still incomplete, we may in many cases nevertheless satisfy ourselves with sufficient accuracy as to the size, position, and motility of the organ; but in cases of difficulty or obscurity it is safest to examine a second time under the best possible conditions.

If upon examining a patient six hours at least after his last meal we obtain the splash by clapotement, we can infer deficient motility. Noting at the same time the lowest point where the splash can be distinctly heard, we may infer as a rule that the lower boundary extends to about that level.

We should then percuss the abdomen with the patient in various positions to verify the results of clapotement and map out the boundaries.

If no splash should be obtained, before proceeding to administer water it is well to percuss with the patient first recumbent, and afterward in the erect posture, to determine the apparent stomach-boundaries while the viscus is still empty. Note these mentally or mark them on the body.

Then have the patient drink ⅛ to ¼ litre of water, and try again to obtain the splash. If it is obtained distinctly after the smaller amount of water mentioned, it raises a question as to the motility, and will also show where to percuss with especial care and delicacy for the lower border.

For the adept in percussion the fingers may suffice to bring out the finer differences in tone, but with a good percussor and pleximeter the task is greatly simplified.

The cut of a new pleximeter devised by myself will be found below. It is wholly made of rubber of medium hardness and is very easily carried in the pocket. The smaller end serves ordinarily as the handle, but in mapping out spaces very accurately or in percussing in narrow spaces, as between the ribs or over the clavicle, especially in children, it is better to reverse the ends and percuss over the smaller part.

Any one of the rubber-tipped percussors usually found in the instrument-stores can be used satisfactorily with this pleximeter.*

Having already made out the apparent boundaries with the stomach empty, we percuss again with it partly filled while the patient stands, or, in the case of persons who are in bed or very weak, sitting upright will usually suffice to bring the fluid contents in contact with the front wall of the abdomen and thus develop a zone of dulness. In going over a new case in this way it is best to give one glass of water at a time, when, if the stomach is atonic, the

* The above cut was published in THE MEDICAL NEWS of July 13, 1895, with a few lines descriptive of it, but is reproduced here because of its importance in connection with the subject-matter of this paper.—B. R.

area of dulness usually extends downward with each successive glass; but if entirely strong, it extends upward only or mainly.

One can begin either above or below, and should then percuss carefully in the median, left parasternal, and mammillary lines from the level of the nipple to the pubes in any doubtful case. Having determined the highest and lowest points of the anterior thoracic and abdominal surface with which the stomach is in contact, we should percuss perpendicularly across the oblique curved line joining these points and forming the left lateral boundary of this epigastric area. Then the right lateral boundary separating the stomach from the ascending colon should be made out in like manner. With the patient erect and the stomach well filled, this is usually a simple matter, the ascending and descending colons and their flexures nearly always emitting a more or less tympanitic note, even when partly filled. If the precaution has been taken to have the colon previously emptied, the contrast with the dull note over the full stomach will be, of course, still more marked. Having the patient lie first on one side and then on the other during the percussion may help to clear up a doubtful question. Filling the colon with air by the double-bulb rubber syringe in the usual manner will emphasize strongly the contrast with the dull stomach-area in the erect position, and filling the colon with tepid water while the patient is recumbent reverses the contrast in a very striking manner, though this is not a feasible undertaking with all patients, since some cannot retain the liquid long enough.

The determination of the upper border or stomach-lung boundary is the most difficult part of the procedure. Usually, however, by trying alternately light and strong percussion, there will be obtained a marked difference in the two qualities of the resonant tone, that over the stomach being more tympanitic. Still it requires much practice to make this out quickly and positively. Occasionally in exceptional cases where the stomach contains very little gas, we may fail at one examination and succeed readily at a second one. This line is sometimes more easily determined after a meal, since then such gases as are present are forced to the upper part and produce more tympany. One needs to bear in mind such possible disturbing factors as a greatly enlarged spleen or enlarged left lobe of the liver; also left-sided pleurisy filling up the half-moon-shaped space of Traube with exudation.

However, there is only one condition at all frequent which is likely to prevent us entirely from determining the boundaries of the stomach by the combination of procedures we have been describing, and that is extreme obesity with great thickening of the anterior abdominal wall. Fortunately, however, this is a condition which does not often coexist with any serious form of gastric disease.

To recapitulate, the following nine different kinds of stomachs can usually be differentiated by this combination of methods:

1. Stomach of normal size, in normal position, and having sufficient motor power.

2. Stomach normal as to size and position, but weak in motility. Gastric atony.

3. Stomach enlarged, but motor power strong. Megalogastrie of Ewald.[9]

4. Stomach enlarged and motility weak. Dilatation or gastrectasia.

5. Stomach wholly displaced downward, but otherwise normal. Not enlarged. Gastroptosis of Glenard.

6. Stomach both enlarged and displaced downward as a whole, but not dilated. Motility good. Megalogastrie with gastroptosis.

7. Stomach wholly displaced downward and dilated. Weak motility. Gastroptosis with gastrectasia.

8. Pyloric end of the stomach displaced downward and swung around to the left, but without dilatation. Often the pylorus is carried down almost, if not quite, into the long axis of the fundus, producing what has been called by Meinert[10], Kellogg,[11] and others the vertical or subvertical stomach, according to the degree of the displacement. This form may be appropriately called pyloroptosis.

9. Pyloric end of the stomach displaced as in No. 8, and also dilated. Pyloroptosis with dilatation.

These several varieties of stomachs may be recognized as follows:

1. Normal stomach. If empty, no splash will be obtainable until after the viscus has been partly filled, and then either none or a feeble one heard, not lower, as a rule, than midway between the lower end of the sternum and the umbilicus—exceptionally to within three cm. of the umbilicus. Percussion, especially with the patient standing after drinking water, will demonstrate the boundaries in normal place.

2. Atonic stomach. The findings will be the same, except that a splash may possibly be heard four to six hours or longer after a full meal, or, if not, the drinking of a very small quantity of water will develop it decidedly. Percussion will show delayed emptying of the organ.

3. Megalogastrie. Upper border will be found in the normal situation. Lower border may be at the level of the umbilicus or even below, but motility good. No splash obtainable six hours or longer after a full meal.

4 Gastrectasia. Splash usually obtainable six hours or longer after a meal and in bad cases at

any time during the twenty-four hours. Percussion shows enlargement of the organ and delay in emptying itself.

5. Gastroptosis. Splash usually rather more easily obtainable than in the normal condition and at a lower level, often at the navel or even considerably below it. Percussion shows descent of both upper and lower boundaries, but no enlargement.

6. Megalogastrie with gastroptosis. Same as in No. 5, except that percussion shows the upper boundary not so much displaced, or if so, then the lower border still further below its normal line. Percussion shows enlargement.

7. Gastroptosis with gastrectasia. Same as No. 6, except that the splash is obtainable too long after taking food or drink. Clapotement and percussion show abnormal delay also in emptying the stomach.

8. Pyloroptosis. Splash obtained usually far below the level of the normal lower border. Percussion reveals the peculiar outlines of the vertical stomach with the pyloric end low in the abdominal cavity.

9. Pyloroptosis with dilatation. Same as in No. 8, except that the splash is usually more pronounced and may be found too long after food or drink. Percussion shows also a widening of the pyloric end of the stomach.

In any of the foregoing cases it may be necessary to inflate the stomach with carbonic acid gas, supposing it to be impracticable to use the tube, or to inflate the colon with air from below.

CONSANGUINEOUS MARRIAGE AS A FACTOR IN THE CAUSE OF DISEASE.[1]

BY E. OLIVER BELT, M.D.,
OF WASHINGTON, D. C.:
PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, HOWARD UNIVERSITY, AND OCULIST AND AURIST TO FREEDMEN'S HOSPITAL.

ACCORDING to the old Levitical law, a man was not allowed to marry a near relative. It was an abomination to the Lord, and if afflictions appeared among the offspring of such marriages, such as blindness, deaf-mutism, idiocy, or physical deformity of any kind, naturally it was looked upon as a direct result of the breaking of this law and a visitation of Divine wrath. However much hereditary and other influences had to do with these abnormalities, consanguinity was ascribed as the cause.

As a result, we doubtless have statistics which attribute disease to this cause much more frequently than the facts warrant; *e. g.*, in a table by Dr. Manning, in three cases in which brother and sister married, there were seventeen children, of whom nine were idiotic, or about 53 per cent. Some would attribute this to consanguinity, but we find that the parents were simple-minded, so heredity partly accounts for the idiocy independent of the consanguinity. The same author mentions twelve families in which the parents were not related, but one or both of whom were either insane themselves or had near relatives insane. In these families there were forty-four children, twenty-six of whom, or 59 per cent., were idiotic.

So in many cases there may be other factors than consanguinity. Many people are inclined to accept, without question or investigation, consanguinity as the cause of nearly all the afflictions which befall the offspring of such marriages.

Scientific men, however, without intending in the *least* to be sacrilegious, are apt to investigate more thoroughly these cases and see if they cannot be explained by natural laws, and there are a number who think, with Mr. Alfred Huth, "that consanguineous marriages, by the mere fact of consanguinity and irrespective of any inheritance, are not injurious to offspring."

In the consideration of this subject, heredity, which plays a most important part, must be considered. We know beyond the question of a doubt that some families have an hereditary tendency or predisposition to certain diseases, such as gout, cancer, tuberculosis, insanity, deaf-mutism, etc.[2] And a "great variety of traits, physical and mental, are of every-day observance as existing in unusual degree in certain families, such as superior or inferior stature, corpulence or leanness, extraordinary

[1] Read before the Medical Society of the District of Columbia, November 6, 1895.

[2] S. S. Herrick, M.D., in the Reference Handbook.

muscular strength, loquacity, precocity in mental or bodily development or tardiness in the same, left-handedness, grace of movement or oddities of gesture. While some families are characterized for such virtues as business integrity, truthfulness, temperance, and frugality, others are equally marked for dishonesty, mendacity, drunkenness, and prodigality."

Now, if two persons marry who have inherited similar characteristics, these characteristics are undoubtedly not only handed down, but are apt to be augmented in the offspring, as we find abundantly illustrated among animals in which distinct breeds are created by the careful selection and mating of animals which have the peculiar traits desired.

This being admitted, we would then naturally expect to find among children of consanguineous marriages the family peculiarities greatly intensified or augmented, whether it be of mind or body, of health or disease. So as a factor in the cause of disease where there is a family predisposition to tuberculosis, cancer, insanity, idiocy, deaf-mutism, blindness, or any other deformity, consanguineous marriage would undoubtedly augment that predisposition, and as near relatives are apt to possess a number of similar defects, such marriage would result in the greater tendency to disease. As a result of atavism or reversion, some trouble may develop which has been latent during many generations.

Then heredity alone should be sufficient reason to prevent two persons with similar hereditary weaknesses from marrying.

In the discussion of this subject two questions arise: First. When there is an hereditary predisposition to a certain disease on both sides, is disease any more apt to occur in the offspring of parents who are related than in those who are not? Second. When there is no hereditary disease of any kind on either side, is the disease liable to occur simply as a result of consanguinity? In other words, is consanguinity of itself a cause of disease? Quite a number of scientific men of to-day deny that it is, holding that the apparent cases are really results of heredity, syphilis, or inebriety.

However, there are many cases of disease among the offspring of consanguineous marriages in which there is no history of syphilis, inebriety, or hereditary tendencies whatever, and where there is nothing to which we can ascribe the disease except consanguinity.

For example, in my own practice I have recently seen two families suffering with retinitis pigmentosa, in which the parents were healthy, but were first-cousins.

There was no history of eye-trouble in either family or of syphilis or inebriety.

In the first family the parents and grandparents were first-cousins. There were three sons and one daughter nearly blind with the disease and three sons and one daughter with good vision.

In the second family the parents were first-cousins with no hereditary diseases whatever. There were four daughters and one son suffering from retinitis pigmentosa, and three sons and one daughter with good eyes; one child died in infancy. Supposing that this infant had good eyes, the result would be exactly 50 per cent. in each family suffering with the disease.

When retinitis pigmentosa occurs it is so frequently found among the offspring of consanguineous marriages that nearly every author of a work on ophthalmology speaks of it as the most common cause. In ninety-five cases of retinitis pigmentosa reported by Liebreich in which the parentage was traced forty-three were of consanguineous origin, or 45 per cent. In twenty-one cases seen by Dr. Frinzel eight were of consanguineous parentage, or 38 per cent.

The following are quotations from well-known authors as to the cause of retinitis pigmentosa:

"In almost a third of the cases the disease occurs in individuals descended from consanguineous parents. Herein apparently lies the explanation of the fact that pigmentary degeneration of the retina is so frequently associated with other congenital anomalies, since these latter also occur as a result of the consanguinity of the parents."—*Fuchs.*

"The disease is markedly hereditary. In numbers of instances consanguinity of the parents of the patient has been found; indeed, the disease has been attributed to this alone. Hereditary syphilis has been given as a possible cause of retinitis pigmentosa, but this has not been proven. The affection is found among deaf-mutes, idiots, epileptics, and in this sense is connected with morbid states of the nervous system. Very often no cause can be assigned. The disease is either congenital or begins in childhood."—*De Schweinitz.*

"It is said to be one of the results of intermarriage of near relatives. This, however, is probably true only in the sense that in any case of in and-in breeding the tendency to reproduce family peculiarities is much strengthened."—*Norris and Oliver.*

"Retinitis pigmentosa appears to have some obscure connection with morbid states of the nervous system. It occurs as Liebreich first pointed out—very frequently in the offspring of marriages of consanguinity. It has been thought to be connected with inherited syphilis, but the evidence on the subject scarcely supports the theory."—*Gowers.*

"It is undoubtedly strongly heritable, and many high authorities believe that it is really produced by consanguinity of marriage, either between the parents or near ancestors of the affected persons."—*Nettleship.*

"Retinitis pigmentosa often affects more than one member of a family, the patients being frequently defective in intelligence or deaf and dumb. Many of them are the offspring of marriages of consanguinity, and in others an inherited syphilitic taint is present, while in others no cause can be assigned."—*Swanzy.*

"The etiology of this disease is not known; it often appears in several members of the same family, as if it were hereditary, and sometimes is coincident with

idiocy or deaf-mutism. A certain number of children affected with this disease are the offspring of consanguineous marriages; others seem to be the subjects of hereditary syphilis."—*Meyer.*

"Retinitis pigmentosa is said to be most commonly met with among the offspring of persons nearly related to one another; but this can hardly be the cause of the disease among the natives of India, as they are scrupulous in observing the restrictions they place upon the intermarriage of relatives; yet we have seen a considerable number of instances of this disease among native patients. It is common to find this affection in several members of the same family."—*Macnamara.*

"It is found in families, and intermarriage of kindred has been considered greatly instrumental in its production. Leber finds about 25 per cent. of the cases within this category. Dr. Chazarain, of Bordeaux, says, in a very able paper, 'On the Marriage of Consanguinity and Deaf and Dumbness,' which is generally supposed to be one of the most constant defects resulting from such a marriage: 'M. Boudin informs us that deaf-mutes are the issue of consanguineous marriages in the proportion of 28 per cent. at the Paris Imperial Institution, 25 per cent. at Lyons, and 30 per cent. at Bordeaux, and that as regards the Jews of Berlin twenty-seven in ten thousand are deaf-mutes, while the proportion is only six in ten thousand among the Christian population in that city;' and apparently, therefore, with great justice, he concludes that the hypothesis of the pretended harmlessness of consanguineous marriages is contradicted by the most evident and well-authenticated facts."—*Noyes.*

Statistics on Deaf-mutism, by Holger Mygind, M.D., Copenhagen, 1894, allow the deduction that in 13,469 total marriages 697 deaf-mutes were born of consanguineous marriages—5.17 per cent.; and, furthermore, that of congenital deaf-mutes in a total of 6903 marriages 759 were born of consanguineous marriages—10.9 per cent. If consanguinity has any effect in the production of deaf-mutism, we would expect to find it more especially among congenital cases; so we do find, according to the above statistics, the percentage in such cases doubled.

Mygge has subjected all the statistics that had appeared up to 1879 to a most critical examination, and came to the conclusion that the issue of consanguineous marriages were absolutely more exposed to idiocy, insanity, and other physiological defects than other persons. He found while in Denmark consanguineous marriages may be supposed to represent three-fourths per cent. of all marriages, 6.75 per cent. of the deaf-mutes admitted into the Royal Deaf and Dumb Institution at Copenhagen, between 1858 and 1877 (altogether 477), were the result of such marriages. If the congenital deaf-mutes were considered alone, then 7.55 per cent. were from consanguineous marriages.

Among 553 Danish deaf-mutes only 3.3 per cent. of those with acquired deaf-mutism were born of consanguineous marriages, while this was the case with 14.6 per cent. of the congenital cases.

The Irish statistics proved that the closer the degree of relationship between the parents the larger was the number of deaf-mute children born. This is confirmed in the Danish deaf-mutes. One marriage between aunt and nephew produced three deaf-mutes. Four marriages between uncle and niece produced eleven deaf-mutes. Twenty-six marriages between first-cousins produced thirty-eight deaf-mutes. Sixteen marriages between second-cousins produced twenty deaf-mutes. Forty-seven marriages between blood-relatives produced seventy-two deaf-mutes.

Wilhelmi could find hereditary influences in only two of eighteen consanguineous marriages with deaf-mute children, and Mygge in only two out of fifteen.

Dr. Bemiss gives an account of 833 marriages between relations in which he finds the following results: In ten cases of incest with parents, or between brother and sister, 93 per cent. of the offspring were defective. In twelve marriages with niece or aunt 75 per cent. were defective. In fifty-six marriages between blood-relations, the issue of blood-relations, 53 per cent. were defective. In twenty-seven marriages between double first-cousins 27 per cent. were defective. In one hundred and twelve marriages between second-cousins 13 per cent. were defective; while in 125 marriages between persons in no way related only 2 per cent. were defective.

From close in-and-in-breeding of animals we find physical and mental degeneration and often deformity. I know of a lady who raised six generations of canary-birds without crossing. In the last brood of four birds one was healthy, while three had their legs growing from their backs and their wings were where their feet should have been.

In a paper by E. F. Brush, he quotes Darwin as saying: "With respect to pigs, there is more unanimity among breeders on the evil effects of close inter-breeding than, perhaps, in regard to any other large animal." Mr. Druce, a great and successful breeder of the improved Oxfordshire (a crossed race) writes: Without change of males of a different tribe, but of the same breed, constitution cannot be preserved. Lord Western was the first importer of a Neapolitan boar and sow; from this pair he bred in-and-in until the breed was in danger of becoming extinct, a sure result, as Mr. Sidney remarks, of in-and-in breeding. Darwin further relates that a Mr. Wright, a well-known breeder, bred a family of pigs in-and-in for seven generations; the number of pigs was reduced at each gestation, and of the offspring thus produced many were idiotic, without sense even to suck, and when attempting to move could not walk straight, until finally one sow was the sole offspring; she would not become pregnant by her sire, while to a stranger in blood she bred at the first trial.

These investigations certainly indicate that consanguinity of itself is a cause of disease, and that

hereditary diseases are much augmented by such marriages.

In an address to the deaf, by Alexander Graham Bell, he says:

"The laws of heredity seem to indicate that a consanguineous marriage increases or intensifies in the offspring whatever peculiarities exist in the family. If the family is characterized by the large proportion of persons who enjoy health and live to old age with unimpaired faculties, then a consanguineous marriage in such a family would probably be beneficial, by increasing and intensifying these desirable characteristics in the offspring. On the other hand, if the large proportion of the family betray weakness of constitution—for example, if many of the children die in infancy and a large proportion of the others suffer from ill health, only a few living to old age with impaired faculties—then a consanguineous marriage in such a family would probably be hurtful to the offspring. A large proportion of the children would probably die in infancy, and the survivors be subject to some form of constitutional weakness."

As there are few families entirely free from constitutional defects of some kind, a prudent person would do well to avoid a consanguineous marriage in any case, not necessarily on account of deafness, but on account of the danger of weakening the constitution of the offspring. Remoteness of blood is eminently favorable to the production of vigorous offspring, and those deaf persons who have many relatives deaf would greatly diminish their liability to have deaf offspring by marrying persons very remote in blood from themselves.

Children, I think, tend to revert to the type of the common ancestors of their parents. If the nearest *common* ancestors are very far back in the line of ancestry, the children tend to revert to the common type of the race. Deafness and other defects would be most likely to disappear from the family by marriage with a person of different nationality.

THE DIAGNOSIS AND TREATMENT OF GOUT.

BY JOSEPH N. BISHOP, M.D.,
OF NEW YORK.

IN a previous paper we dwelt very extensively upon the theory and distribution of gout. Interesting though it may be to theorize as to its cause, the practical outcome of such study should be the recognition of the disease in its various forms and the application of a proper plan of management. The subject naturally divides itself into the diagnosis of acute attacks of gout and of the gouty diathesis, constitution, habit, or whatever else we choose to call it.

Acute gout arising for the first time in a comparatively young person can very easily be overlooked by us in this country because it is not at all common in our experience. The points to be considered are the time of the attack, the location of the pain, its character, the nature of the inflammation, and the fact that the inflammation is followed by desquamation of the cuticle. The attack usually occurs without previous foreboding in the early hours of the morning. The pain, located, as a rule, in the metatarso-phalangeal joint of the great toe, is very severe in character. The tissues of the joint will be acutely inflamed, swollen, and intensely congested. Accompanying the attack there will be a slight rise in temperature, which increases slightly after the attack has lasted a while. Toward the afternoon of the following day the fever subsides and the pain is a good deal relieved, but the symptoms recur the next night, and the attack goes on in this way often from five to eight days, gradually wearing off. The inflammation may involve the great toe of the opposite foot or other joints. Now there occurs what will confirm our diagnosis, and that is the desquamation of the epidermis of the part inflamed. The term "suppressed gout" is applied to a series of symptoms not typical of gout, but which occur in a person subject to gout, and which from strong *negative and positive* evidence we suppose to be gouty in origin. These attacks of suppressed gout are worthy our close study because they must occur sometimes in our practice, and can so easily be overlooked. They may immediately follow an attack of acute gout, or replace an attack. The patient may have severe vomiting, pain, diarrhœa, and profound depression, or there may be cardiac failure, manifested by dyspnœa, irregular action of the heart, and pain referred to the heart or to the left shoulder. We should remember that these attacks of so-called suppressed gout may occur independently or replace an attack of acute articular gout. Here it is that a great difficulty of diagnosis occurs, and the best that we can do is to keep this in mind as the possible cause when we see obscure, severe, and often fatal cardiac attacks accompanied by extreme dyspnœa, with failure of the heart's action in force and rhythm. Our training in this country leads us to attribute all these cases to uræmia, and we go so far as to classify cases in which there is an absence of albumin in the urine and many other of the typical signs of kidney-disease. It would seem that at least a few of these cases were cases of suppressed gout.

Nor is the diagnosis of the gouty diathesis easy or one upon which all observers will agree in every individual case. Just what the condition is from is also a matter of discussion, but that there is such a condition is not a matter of dispute.

Dr. William Draper said, in a discussion on gout occasioned by a previous paper, that the "gouty habit is a constitutional vice, a vice of nutrition." We say that a man has gout because he has too much uric acid in his blood; but the close rela-

tion between diabetes and gout suggests the idea that the former is a condition of imperfect combustion of carbohydrates, and the latter of proteids. This seems to give a good working hypothesis for the understanding of these diseases. In the same discussion Dr. F. P. Kinnicutt said: "I believe that gout exists in America to-day to a very large extent, and I should say that probably it exists more frequently in the irregular than in the typical form. We do not see so much in the hospital as in private practice. What I see in private practice perhaps more frequently than any other manifestation of it is both the typical and irregular forms in women, particularly as they approach the climacteric. I think that about the approach of this period you will find in very many women all the manifestations of gouty trouble."

The diagnosis of chronic gout following a series of acute attacks and gradually settling down to a permanent condition is easy enough, but this is not the beginning that we usually find. Like Bright's disease, a very large number of cases are gradual in onset, and it is hard to say just where they began. This is especially true of the cases in which the articular symptoms are not very marked. In articular gout the picture of a chronic case is very typical. We have the deposits of concretions about the joints with the skin over the tophi becoming stretched and often discharging so-called chalkstones. The subject of such a condition is usually anæmic, poorly nourished, and in addition has those signs which follow in endarteritis, namely, high-tension pulse, an increased quantity of urine of low gravity and containing a trace of albumin. In studying hospital reports some years ago I was struck by the extreme rarity of diagnosis of gout and the frequency of the diagnosis of chronic diffuse nephritis. It would seem that the microscope had concentrated our gaze too much upon kidney-pathology. It is a teaching of some, or at least the impression given students, that many of these cases are primarily cases of nephritis, and that scleriasis of the vessels with the accompanying condition is secondary. Certainly a good many of these cases are cases of gout, or at least of the gouty diathesis, and should be treated, especially at the beginning, as cases of lithæmia. The importance of early diagnosis is that the avoidance of sclerotic conditions depending upon gout depends upon a proper management of the underlying vice of nutrition.

The discussion of the diagnosis of gout would not be complete without a consideration of some of the more irregular manifestations. These may be nervous, gastric, cutaneous, pulmonary, or may affect the organs of special sense. Their irregular manifestations are as often due to hereditary tendencies as to acquired gout, hence we see them often in very young people. The gouty habit or lithæmic state may even appear in infants. Infantile eczema may sometimes be due to hereditary gout when it is unusually obstinate to treatment. In older people cutaneous affections are very closely allied to this constitutional vice. So firmly is this belief held in these days, that no one would think of treating chronic psoriasis without attention to diet; but skin-affections are not always gouty, and the effect of diet and the modification of other conditions of the system upon the course of the disease should be studied before arriving at the conclusions that any particular skin-disease is due to gout.

While writing this there comes through the mail a pamphlet on psoriasis, in which Dr. L. Duncan Bulkley, in speaking of the relation between gout and these very troublesome skin-affections, says:

"It is often very difficult to determine with certainty the underlying causes which operate to produce the eruption, for it is observed in those presenting widely diverse conditions of life and under the greatest variety of circumstances. It develops with about equal frequency among the poor and the rich. Not only will it appear after exhaustive diseases, after pregnancy, and in those debilitated by various excesses, but it comes also in subjects who are apparently in the best of health and enjoying the surroundings of a healthy and apparently proper life. No single cause or element, or any combination of causes or elements, can be traced in every case.

"The evidence increases, however, that it is more or less closely allied to the blood-states which are known as the gouty and rheumatic."

The gout-factor in the production of pulmonary affections and affections of the organs of circulation is also pretty clear, for gout is certainly often a factor in the production of chronic bronchitis and in the sclerosis of vessels and valves, which is so familiar as the cause of those diseases of the heart and bloodvessels which are of gradual onset. That chronic bronchitis is often due to gout might be inferred from the fact that it occurs so often in gouty people, and that it is sometimes ameliorated by a course of treatment for the underlying constitutional state when more direct methods have had but little effect. Gastro-intestinal disorders are often of a gouty origin. This is especially true of attacks of biliousness in which the tongue is dirty, the bowels constipated; headache and all the other usual symptoms are not only present, but rather persistent. When these bilious attacks occur with unwonted frequency and are not modified by ordinary treatment, it is well to investigate for other evidences as to the gouty diathesis. To some of the nervous manifestations we have already alluded in quoting some remarks of Dr. Kinnicutt.

The nervous manifestations of gout may be divided into two classes, the immediate and the remote. The immediate are such as are due to the effect of

sodium urate circulating in the blood and coming in contact with nervous elements or being deposited in them; the secondary effects are due to the gouty ravages upon tissues in the neighborhood of nerves or upon the bloodvessels by which the large nervous centres are nourished. Perhaps the commonest manifestation of gouty state in its recurrent form is a migraine. The investigations of Haig caused him to come to certain conclusions after elaborate clinical and chemical investigations. After trying a great variety of alternations of diet, he gave up all butcher's meat and replaced it by milk and fish. On this diet the headaches disappeared by the intervals becoming longer, until finally he went eighteen months without an attack of notable severity. In searching for the cause of this phenomena he discovered the relation between his headache and the excretion of uric acid, and means by which he could control the excretion of uric acid from day to day, or from hour to hour, and that in altering the uric acid he could alter the symptoms relating to it. He noticed that when he produced the headache, mental depression, etc., there was an increased excretion, and when he stopped the plus excretion with an acid he removed all these symptoms. But he noticed that in curing the headache by giving the acid he produced a certain amount of shooting-pain in the joints, the meaning of which probably was that the uric acid which failed to appear in the urine must have been held back in the joints and produced pains. The headache depended upon the absolute quantity of uric acid circulating in the blood.

Haig's interpretation of the phenomenon is as follows: He supposes that gouty symptoms are due to an accumulation in the body of uric acid depending upon a diminished excretion. He points out that if excretion falls behind secretion by a minute quantity, in the course of time there will be an accumulation. He supposes that so long as this accumulation is quietly stored up in the tissues there are no constitutional symptoms, but when for any reason this is liberated and circulates in the blood the symptoms appear, and naturally enough an excess appears in the urine. This theory certainly explains very well the increased excretion that he observed at the time when symptoms were present or imminent. This also explains the periodicity of attacks. He believes that in persons in whom the balance of secretion and excretion is but very slightly deranged there is a very gradual accumulation, and that such persons will suffer from gout in some of its more obscure forms after years have elapsed.

In practice, however, we would not wish it to be thought that gout is by any means the cause of all or even the majority of cases of migraine. This most interesting affection, in all probability, has a number of very different origins. Neuralgia affecting the sciatic nerves, the intercostal nerves, the fifth nerves, or, more rarely, other nerves, are often gouty in origin. The gouty subjects are also liable to neuralgic pains of a shooting, drawing character, lasting a moment and then disappearing in almost any part of the body. They also suffer from visceral pains of a neuralgic character. A true neuritis most commonly affecting the sciatic nerve is common in gouty subjects, especially if alcoholic. In speaking of the more or less indefinite nervous symptoms of gout, Gowers says "that cases which may be regarded as functional are those in which symptoms, commonly subjective in character, result from some morbid blood-state."

Occasionally there is definite failure of power, lasting for a few days or weeks, without objective symptoms, and passing. But the most common symptoms for this cause are sensory and subjective, feelings of tingling and formication in the legs, dull aching, and sometimes actual pain; this is usually transient, but occasionally continues for some days or weeks, varies in position, but in gouty cases often felt in the heels. Symptoms due to morbid blood-states, like other symptoms of the same class, are especially common in persons who inherit a tendency to gout, but have not suffered from attacks of definite arthritis. Indirectly due to gout are the effects of the interruptions of circulation which go with gouty endarteritis. The thickening of the cerebral arteries may give rise to attacks of dizziness, temporary loss of consciousness, and even impaired mental conditions. When a condition of endarteritis sufficient to cause these symptoms is present, there is, of course, great danger of thrombosis and an accompanying destruction of brain-matter, with symptoms corresponding to its location.

Of the effects on the special senses, due to gout, we will speak briefly. It may attack almost any of the tissues of the eye. As a cause of conjunctival irritation it seems to be quite frequent. Iritis, though perhaps more commonly rheumatic, may still be due to gout. Even glaucoma has been attributed to it, but the evidence is not very strong.

Gout as a cause of deafness is sometimes due to urates being deposited between the layers of the membrana tympani. Gouty subjects are especially liable to inflammations of the throat and larynx, and to catarrhal conditions generally, but there is no direct evidence that it is more than the increased liability which would come with the depressed vitality of a constitutional disorder.

The manifestations of gout have not by any means been covered by this enumeration, but we must pass now to a brief consideration of the man-

agement. The word management, as a name given to our efforts to bring about a cure of gout, is better than the word treatment, because treatment carries with it a trace of an idea of a specific plan of medication. It is a trite remark that the management of gout is chiefly a question of hygiene, and that though the value of drugs cannot be disputed when applied to proper cases at the proper time, still no one drug is always available. To a condition like this we are apt to apply the statement that its management is chiefly a question of hygiene. A good many persons, both laymen and physicians, fall into the error of supposing that a hygienic treatment is easy of accomplishment. This is a deep error. The cure of a disease by the modification of patient's surroundings and the habits of action of his organs may well tax the patience, knowledge, and ingenuity of his doctor. Hygienic treatment includes not only the modification of air, mode of life, food and drink, but the skilful use of drugs, which are directed to the improvement of the physical action of the organs. It does not seem quite philosophical to include tonics, blood-foods, and laxatives under the head of a drug-treatment of the disease.

The first question that arises is that of food. We must modify the popular notion in regard to different classes of food. We are not in a position to draw a line between carbohydrates and proteids. Clinical evidence is brought forward by Dr. William H. Draper and others that some gouty patients do well on animal-diet, controverting the theoretical conclusion that meat is to be avoided. The safest hypothesis upon which we can work is that in gout there is an impairment of the chemical powers of the body, which in different patients affects somewhat different processes. Some hold that it is a question of deficient oxygenation, so, of course, we think immediately of remedying the defect by supplying more oxygen. This we attempt, but we must also take pains that the amount of these foods, concerning which there is a failure of chemical action on the part of the body, shall be in as small a quantity as possible.

In discussing the previous paper already alluded to at the New York Academy of Medicine, Dr. William H. Draper said:

"Shall he confine himself to starchy foods and take as little proteid food as possible, or shall he take proteid food with the proper proportion of starchy food? My own experience leads me to think that a gouty person does best upon a diet in which there is a good proportion of proteid food, but that he should have a fair amount of starchy food as well. Gouty persons digest proteids freely, but the carbohydrates are exceedingly difficult of digestion.

"Now, in regard to sugars, sweets of all kinds, in gouty persons, what has been your experience? There is an inability in gouty persons to digest a large amount of sweets; often they have to forswear sweets. They may indulge in spirituous drinks and suffer no inconvenience, but if they take fermented wines they suffer, and how? They have eructations of wind and are made very uncomfortable by it. Or they may suffer some of the nervous symptoms of gout as a consequence of a glass of wine or beer. Many gouty persons learn to shun the fermented preparations of alcohol. The gouty person may take distilled liquor, while he cannot take it as a fermented preparation. This is, I think, a very striking fact in the history of gouty people and one that complicates very much a uric-acid theory of the disease.

"Now, in regard to starches. It is a very curious feature—but it is one which experience confirms—that there are persons who cannot take much starch, who are made uncomfortable thereby by nervous troubles as well as by the physical distresses to which they render themselves liable. This is especially true of potatoes. The simple injunction, 'Don't use potatoes,' is often of great value to the sufferer from gout. There is something in the vice of nutrition from which gouty people suffer, which is above and beyond the question of ingestion of food. What this is we do not now understand; but I believe that some day we shall understand why it is that gouty people, who ought to eat starchy food, cannot eat of it, and can eat proteid food."

After all, the diet which Dr. Draper has found by his long experience to be best can be brought within a line of theory by considering that by not overtaxing the digestion with carbohydrates its forces are more at liberty to take care of the proteids. We will not attempt at this time to give a dietary, because in truth that must to a large extent be worked out for the individual case. We must study food from the theoretic side, but in the presence of the disease each patient must be studied by himself.

The drug-treatment of gout is not a specific treatment. After we have controlled as far as possible the supply of foods to be taken care of, we attempt to modify favorably the chemistry of the body, and here the probable philosophy of mineral-waters becomes plain. Nearly all chemical operations are carried on with water as the vehicle for the chemical agents and reagents. Every chemist knows that in seeking a chemical result the reaction of the fluids—that is, its degree of acidity or alkalinity—must be right. Now by supplying to the system fluids in abundant quantities, especially if these fluids tend to modify favorably the reaction of the system, we are certainly benefiting the chemistry of the body.

Lithia seems to have vindicated its right to a place among useful drugs in gout. Its action is probably not, as was formerly supposed, principally by increasing the solubility of sodium urate, but it seems to have also a catalytic action; that is, by its presence it favors the action and reaction of the fluids of the body to a degree out of proportion to its amount. In giving lithium, and this remark may be applied also to other drugs, it should be given in definite amount. There is no magic in native mineral-waters. Artificial waters are just as good, and have the advantage of a definite formula and safety from possible infection in rural neighborhoods. We would not think it necessary to unfold this doctrine to a

patient to whom we thought the surroundings, the mode of life, and mental effect of a watering-place were necessary, but scientific truth is not modified by popular beliefs. And the verdict of the laboratory upon the absence of any magic combination in native waters is positive.

Colchicum has been shown by clinical experience to be of great value in controlling the symptoms of gout. It relieves the pain of acute attacks and modifies the course of chronic cases. It is an English tradition, still held, that the suppression of acute gout by colchicum is liable to the production of dangerous internal diseases. Between the paroxysm colchicum can be given from day to day with apparent benefit. Piperazine is a drug that is attracting so much attention that it cannot be passed without mention, but conclusions are not yet positive. Besides these drugs iodide of potassium in chronic gout is the only one well established. The drug-treatment of gout is so much a question of adapting the well-known therapeutic agents to particular conditions that details are best left to individual judgment. Thus we see that gout is a disease which may manifest itself in a great many different ways, and the recognition and management of which must always be of great interest to physicians in every department of the profession.

THE RELATIONS OF RACE AND CULTURE TO DEGENERATIONS OF THE REPRODUCTIVE ORGANS AND FUNCTIONS IN WOMAN.[1]

BY DANIEL G. BRINTON, M.D.,
OF PHILADELPHIA.

THE results of degenerations of the reproductive organs are of equal interest to the physician and sociologist. The former finds in them the fertile sources of diseases involving the whole system as well as the special portions involved, while the latter must trace to them many of the pathological phenomena which appear in the body politic.

For many years the diminished fertility and increased ill-health of American women have attracted the attention of observant medical men in the United States, notably shown in the statistics published by Dr. Nathan Allen, of Massachusetts. In France the stationary character of the population or its actual retrogression in number has excited the alarm of patriotic men, as is illustrated by the work of the Marquis de Nadaillac, entitled *The Nation's Danger* (*Le Peril National*). It is an error to suppose that the small families or total childlessness of many marriages among the wealthier classes of France and the United States is due mainly to Malthusian principles and "preventive checks." It occurs also where these are not adopted, and has a far deeper root than the love of ease and freedom from maternal care.

This has been recognized by not a few social philosophers, as, for instance, Herbert Spencer, Schaaffhausen, and others, who have set up the maxim that the increased mental and moral development of women in modern times necessarily leads to degeneration of her reproductive powers by diverting from them the chief activity of her nervous system.

A comparison of the birth-rate between the married women of higher culture in France and the United States with that prevailing in primitive conditions seems to support this view. The observation of Dr. Boas among the native Indians and the half-breeds on our reservations shows that the married women of forty years of age have had as a rule seven to eight children apiece; whereas in the class of Aryan whites referred to five accouchements at term by that age would seem to be an average. To be sure, among the whites, there is a considerable difference between the upper and the lower classes, and between those of one stock and another; but these facts do not militate against the maxim above quoted.

It does not require arguments to prove the largely increased prevalence of uterine displacements and diseases in highly cultured women, both married and unmarried; nor to emphasize the well-known and remarkable ease of parturition enjoyed by the savage woman in contrast with her civilized sister. We must look upon these as parts of the complicated processes of domestication. The same contrast is seen in the lower animals. The high-bred Silesian ewes of Saxony can scarcely drop their lambs without artificial assistance; "pedigree" cows, bitches, and mares are always greater sufferers in natural labor than the lower and wild varieties, and the mortality among them from the sequelæ is higher.

If we seek to analyze precisely what factors lead to this condition, we may classify them as follows:

The Pelvis. The shape of the pelves of the two sexes differs but slightly before puberty. At that epoch the following changes should take place:

1. The pubic arch of the female should assume a wider span, increasing from an angle of about 60°, which it retains in the male, to about 80°.

2. The coccyx should retain its mobility, which becomes lost in the adult male.

3. The horizontal diameters of the pelvic cavity should increase, giving the basin a more extended capacity.

In the perfectly developed modern white woman these changes take place; but they occur in a much

[1] Summary made by the author for THE MEDICAL NEWS of a paper read before the Anthropological Section of the Academy of Natural Sciences, Philadelphia, January 10, 1896.

less degree in the women of the lower races. Among the Australians and Indonesians it is often impossible to distinguish between the adult pelves of the two sexes. But in highly civilized conditions the development of pre-natal life is more rapid and complete, and space is demanded for its activities. Especially the head of the fœtus at term is larger, and a wider pubic arch is required if the child is to be born alive. Hence it is that the span of the pubic arch in woman becomes the criterion and the necessary condition of racial progress—of the evolution of the human species.

The Menstrual Function. It seems an accepted fact among gynecologists that a high moral and intellectual education tends to postpone the appearance of the menses. That there is also a positive increase in the number and severity of cases of dysmenorrhœa and sympathetic catamenial disturbances among the higher classes is generally acknowledged. Especially may attention be directed to the prolonged and troublesome symptoms connected with the climacteric period. There can be no doubt that these, which incapacitate so many patients for years, are almost unknown in primitive and simple conditions of life. They are the reflex of debilitated function.

The Lacteal Function. A woman under her natural relations should suckle her own children, and is the better in health for doing so. Obstetricians are, however, well aware that it is by no means selfishness or lack of maternal feeling which obliges so many mothers among us to have recourse to wet-nurses or "the bottle." It is that their milk is insufficient in quantity or deficient in quality, or the strain of lactation is too severe on their constitutions. There is, in other words, an obvious impairment in the function of lactation.

The Muscular Structure. Tedious labor and inefficient pains are frequently caused by a lack of development of the uterine muscular fibres. They are common symptoms of parturition among cultivated classes and the higher races; scarcely known among the American Indians and the African negroes. This condition is related less to the general muscular force than it is to a diminished nerve- and blood-supply to the genito-urinary system.

Undeveloped and Adherent Clitoris. The clitoris is well developed in most anthropoid apes and also in the negro race. Among the Hottentots the labia minora and præputium clitoridis are sometimes eight to ten inches long, forming what is called the "Hottentot apron." On the other hand, in Aryan American women the clitoris is very small, as a rule, and the prepuce often adherent. This fact has been recently pointed out by Dr. Robert T. Morris, of New York City, in a note to his "Lectures on Appendicitis." His investigations prove that almost 80 per cent. of Aryan American women have preputial adhesions, and that this condition, through reflex action, tends to produce such an impression upon the nerve-centres that the whole sexual ap paratus is influenced toward degeneration. The Semitic women in this country, on the other hand, show very little tendency to this condition, and Dr. Morris raises the inquiry whether this does not indicate that, as a rule, they are destined to outlast the Aryans?

Sexual Feeling. Deficient or absent sexual feeling predisposes to infertility, and must be regarded as a degenerative symptom. Whether or not the cultured women of the present day have materially lost this feeling, or only keep it more under subjection, it is not easy to decide. Special students of women, such as Ploss, Bartels, and Ellis, speak in favor of the latter view; while Spencer and many others assert that sexual passion in woman has decidedly diminished under civilization. The novelist, Henry James, an acute observer, calls the average New England girl "passionless." Certainly, compared with primitive life, the woman of to-day reveals few signs of sex-feeling. The American Indian women were often subject to epidemics of desire, and the Bacchantes of ancient Greece gave unrestrained liberty to their erotic longings. Only in sexual perverts and distinctly pathological instances do we see anything of the kind to-day. The inference is reasonable that not only has the sexual passion decreased in women, but often to such an extent as to render them indifferent or averse to marriage, and thus to reproduction.

The conclusion from such facts forced upon us is that a series of changes has been gradually taking place in the reproductive organs and functions of woman, the general tendency of which is to reduce her procreative capacity, and that these are more permanent and extended in the Aryan stock than elsewhere.

CLINICAL LECTURE.

CLINICAL LECTURE ON INSANITY.[1]

BY RALPH A. GOODNER, M.D.,
OF ANNA, ILLINOIS;
ASSISTANT PHYSICIAN TO THE ILLINOIS SOUTHERN HOSPITAL.

GENTLEMEN: The first two cases I will present to you I consider interesting, because in many respects they present similar symptoms, yet belong to entirely different forms of insanity. This is L. C., this J. O., both about thirty-two years of age, farmers, education limited, fair physical condition. L. C. has been insane about two years, and his mother was insane. J. O. has been here since last April, and has one imbecile sister. I

[1] Delivered before the Southern Illinois Medical Association at its Twenty-first Semi-annual Session, held at Anna, Ill., November 22, 1895.

know nothing of his history except what I have stated. We have probably heredity in both cases.

Now for the similarity of symptoms; both have delusions of persecution of a religious nature. L. C. says that he has committed the "unpardonable sin," that there is not any hope whatever for his salvation, and that his soul is hopelessly lost. J. O. says that he has been a very wicked man, that he is the chief sinner, and that his sins have been great and many. Each feels that he is imprisoned in this hospital because of his sinfulness; that this is the Lord's punishment. Both are emotionally depressed; their faces express that fact. There is in neither case any excitation of ideas or emotions. There is no impairment of memory or will-power. On any subject but religion they speak sanely. Now, gentlemen, so far our pictures are quite similar, and I choose these cases because the same diagnosis has been made in both—erroneously, however.

FIG. 1.

J. O. L. C.

Now for the dissimilarity: L. C. does not admit any possibility of his soul being saved. J. O. is in doubt, and is constantly debating the question as to his eternal welfare; sometimes feeling hopeless, again hopeful.

There is more depression in L. C.'s case. He prefers to be alone. J. O. is more companionable. L. C. does not think that his punishment will atone in any way for his sins. J. O. thinks the punishment will in some way redound to his credit or advantage. This is characteristic of this form of insanity; no matter what they consider the persecution or whom the persecutor, they usually think it will bring them some credit or advantage in the end. L. C. believes himself worthy of his sorrow, while J. O. thinks that his punishment is too severe and is more rebellious.

L. C. thinks that anyone who has sinned as he has would be lost. J. O. thinks he is the chief sinner; is the persecuted of mankind. Do you not see how his egotism crops out, even in his persecutive delusions? L. C.'s conversation on any other than religious subjects is more or less colored by his delusions, but J. O.'s is not.

Now, gentlemen, we come to the physical signs: L. C. has a well-shaped head, measuring twenty-two and one-half inches in circumference, well-developed frontal region, and symmetry of head and face. J. O. has a head-circumference of only twenty-one inches, rather low and narrow forehead, prominent cheek-bones, small ears, protruding lower jaw, and on opening his mouth I find a saddle-shaped palatal arch. In fact, the physical marks of defective development.

L. C. is a case of melancholia religiosa. J. O. is a case of paranoia religiosa, in the persecutive stage.

This case of J. O. is in a transitional stage. Were it fully developed the differential diagnosis would be a very simple matter, because then they would be exactly opposite types of insanity.

One of these days J. O., because of a visual hallucination, a dream, vivid emotional experience, reading of some passage in the Bible, or some fortuitous circumstance, will believe himself to be a prophet, the blessed of Heaven, or a Christ. His emotions will become pleasurable, ecstatic.

Gentlemen, before introducing some cases of paranoia, just a few words. Paranoia is a form of disease occurring in one of a congenitally defective nervous organization, which manifests itself by logical or systematic delusions of persecutions and self-exaltation without excitation of ideas or emotions, impairment of memory or volition.

There are infinite types of paranoia. The one I now introduce to you has delusions of both persecution and grandeur. This case is fully developed.

This is H. K., a young man with a bright, receptive mind, aged twenty-four years, admitted only a few days ago, duration of disease four years, always been eccentric. I have no history as to heredity. You will notice he has a poorly developed head, the circumference of which is large enough, being twenty-two and one-half inches, but the antero-posterior diameter is out of proportion to the lateral. His frontal development is deficient, and out of proportion to the occipital.

This patient has the delusion that he is a second Christ, that he has a mission to perform as yet not known, that will be revealed later. He is egotistical and thinks he is persecuted by his mother and brother, who are jealous of his superior talent and genius, and would much prefer these blessings had been bestowed upon a brother who is now attending the University of Michigan. His delusions are systematized and limited, which should be the case in paranoia. On all other subjects he speaks intelligently. This young man otherwise is really bright. He completed his education at one of our State normals.

The next case of paranoia is H. F., whom we call "Professor," an appellation of which he is very proud. He is forty-seven years of age and has been here twenty-five years. He was a school-teacher. His father was neurotic.

"Professor" has fixed, egotistical, and persecutive delusions. I will ask him to tell you what he thinks of himself.

Professor: "I am the smartest man in the world and as superior to the ordinary man as man is to the lower animals. I am destined to be the progenitor of a new race, just as Adam was of the people who now inhabit this world, but I have always been persecuted by the witches."

I will now ask the "Professor" why he thinks he is persecuted by the witches. I do this to illustrate a systematized delusion, one that is explained and defended. In acute mania or paresis the delusions are unsystematized, and if I ask such a patient the question, "Why do

you think you own the world?" etc., he cannot give me any plausible reason.

Now, Professor, tell the gentlemen why you think you are persecuted by the witches. Professor: "Well, you see it is like this: The witches have a power over me and will not give me a chance to marry because they fear I will start a new, superior race of people who will be able to cope with and overpower them."

"The Professor."

This case well illustrates one thing Dr. Runge, of St. Louis, told you this morning, namely, one suffering from paranoia does not usually drift into dementia as do the other forms of insanity, at least if he does the progress is slow. This man has been insane twenty-five years, and is just the same now as when admitted so far as mental ability is concerned.

This is H. T., a different type from the preceding ones. This is erotomania, so called, but it is only a form of paranoia. His age is thirty-one years, occupation teacher, paternal aunt insane, and father intemperate. He has been here and at Jacksonville a number of years. He is one of those fellows you often see whose egotism finds vent in aspiring to the hand and love of a lady far above him socially and financially. They never become discouraged, but think and dream of their loved ones constantly. They are often given to poetry. This man writes letters and poetry to a lady of social prominence, which, of course, we never send.

If he has any delusions of persecution, I have never been able to detect them. Perhaps earlier he did, and has lost them, for it is sometimes the case that the delusions of persecution become effaced. It was not so in "Professor's" case, however, he having retained his twenty-five years.

This is W. R., aged twenty-nine years, admitted eighteen months ago, always considered peculiar. His mother was insane. He has delusions of persecution, differing only from J. O. in that his are not religious in character. He imagines every now and then that some other patient, usually a quiet, inoffensive one, "has it in for him," as he expresses it. He will interpret a whisper or gesture that has no relation to him as inimical, and plead to be removed to another hall. Otherwise he is bright, active, and seemingly sane.

He, as well as J. O., is probably in a transitional stage, and later will develop egotistical delusions. Even now, the attendants tell me, he is inclined to be conceited and feels that he is superior to other patients.

The next case is C. F. Nothing is known of his history; was a tramp picked up in Fayette County and brought here. He says General Grant appointed him Commander-in-Chief of the United States Army and Navy. I show this case because his delusions of persecution depend upon an hallucination; *i. e.*, he says his enemies are trying to keep him out of this office, and have been trying to poison him; and he thinks this because he imagines that he tastes the poison in his food, an hallucination of the sense of taste. So much for paranoia.

Now a few words about paresis before I show you some interesting cases. The word paresis has several synonyms, namely, general paralysis of the insane, paretic dementia, dementia paralytica, and in popular language "softening of the brain," although this is a misnomer, because while it is true the consistency of the brain is less firm, there is never a true necrotic softening. Paresis is a structural disease of the brain; briefly, it is a degeneration of the cortex and a low-grade inflammation of cortex and membranes.

It is a disease displaying slowly increasing mental impairment, disorders of muscular movement, disturbances of higher reflex action, physical and mental decay.

The principal causes are syphilis (three out of every four cases we receive having syphilitic histories), intemperance, excessive venery, indirect physical and emotional causes, and trauma. In other forms of insanity we find ordinarily mental symptoms only, but in paresis we have both physical and mental well marked.

The principal mental symptoms are delusions of grandeur (although they are sometimes depressive, or the two may alternate), change of character, loss of memory, and impairment of volition. The emotions are usually exalted, but they too may be depressed.

The most prominent physical symptoms are inequality of pupils, difficulties in articulation, inco-ordination, muscular tremors, epileptiform and apoplectiform convulsions, and finally paresis.

The first case I show you is R. R., aged thirty-three years, occupation brakeman, duration eighteen months, syphilitic, intemperate, Keely graduate, no heredity. These cases usually do not show hereditary histories. They have in most cases well-developed heads and brains. There are three stages of paresis: First or prodromic; second or stage of expansive or depressive delusions, accompanied by well-marked physical symptoms; third or stage of dementia.

This man is in the second stage. I will ask him to tell you what he owns. He says "The world, etc." You will notice how he drawls his words, hesitates in speech, the excessive motility of facial muscles, the tremors. Now while he walks please observe the ataxic gait—how his feet are kept apart to widen the base of his support. I test his eyes and they do not respond to light or accommodation; his patellar reflex, you see, is abolished.

The next case is A. A., aged thirty-four years, occupation merchant, no heredity, duration eighteen months, syphilitic and intemperate. He is also in the second stage. His delusions are not quite so extravagant and

his memory much better than the preceding case, but on asking him to talk he tells you what a scholar he is—reads, speaks, and writes all languages.

You notice, as in our preceding case, the well-marked physical symptoms, namely, difficulty of articulation, prolonging his words, tremors, ataxia, and loss of patellar reflex. His face presents a soggy appearance, and this is often present in these cases. When he came here he said he would pave the streets with gold, etc.; but after being here several months he had a remission, and all mental symptoms disappeared. And here let me say, in these cases remissions are often seen for a few months or even years. Their friends often begin to think they have recovered, but it is a false hope.

The physical symptoms, though not so pronounced through the remissions, usually linger to some extent, as is shown by the tremors, gait, and speech.

The next case is C. W., ex-member of the Legislature, abstracter, a wealthy and prominent man, who has been very intelligent and highly educated, aged forty years, duration three years, no heredity, syphilitic, intemperate, and in the second stage. He shows a general mental weakening, and is more emotional than the preceding cases. He has had delusions of grandeur, but has not now. You notice the physical symptoms are not marked. When he speaks, however, you see excessive movement of the lips. This case is slower in progress than the others, and he is much more destructive. You know the average duration of life—for this is a fatal disease—is only three years. They are usually not committed to us until they have been paretics for some time. The average duration of hospital-life is only twelve or eighteen months.

The next case is L. C., merchant, aged forty-three years, no heredity, duration two years. He is not syphilitic or intemperate, a man of good morals; so we must look elsewhere for a cause, and here we have it. You remember I mentioned trauma as one cause. Well, here is a linear depression on this man's forehead, caused by a blow which preceded this attack. When I came here, less than three years ago, they had but one case of paresis, and it also developed from a traumatic cause. Since then we have admitted twenty-two cases, so it seems to be decidedly on the increase in our territory.

This case of L. C. I show you to illustrate a case passing from the second into the third stage. This man thought he had millions only a few weeks ago. His talk now is incoherent, and he is rapidly passing into dementia.

This case well illustrates the necessity of an early diagnosis, not only because remedial or surgical measures might be more successful, but so you can warn their friends of the possible line of conduct such cases may pursue. This man, before his condition was known to the public, feeling so wealthy, burned notes and money, gave too much change in return, and other unbusiness-like methods, until he became bankrupt.

The next case is L. K., aged thirty-two years, butcher, duration two years, syphilitic, intemperate, no heredity, and a Keely graduate. We have about five cases of paresis who have taken some one of these "whiskey-cures," and the "cure" is often blamed by their relatives for causing the insanity; but I believe the soil has already been prepared by the syphilis, by the years of intemperance and excessive venery, and that they would have developed paresis anyway. Again, if it is due to the "cure," why is it the other forms of insanity do not develop? Why should my cases who have taken the "whiskey-cure" each give a history of syphilis and intemperance?—the very causes of most cases of paresis, if the "cure" is the causative factor. I give this only as my own limited experience; other observers may have had a different one.

This patient has an exaggerated patellar reflex, quite opposite to the others, this being due to the involvement of the inhibitory fibres which pass from the cortex to the anterior columns of the cord. He also has contractures and ankle-clonus, so that the lateral columns are also involved; and that reminds me I had a very interesting case of ascending or spinal paresis to show you, also a case in the prodromic stage, but both were removed on furlough a few days ago.

I thank you, gentlemen, for your attention.

CLINICAL MEMORANDA.

A CASE OF BRONCHO-PNEUMONIA IN THE NEWBORN.

BY HENRY BIXBY HEMENWAY, A.M., M.D.,
OF EVANSTON, ILL.

A FEW weeks ago I was engaged by a healthy young couple to attend the wife in her second confinement. Notice that my services were required was served upon me on the afternoon of November 3, 1895. I called about 5 P.M. and found Mrs. A. in the parlor talking with the nurse, who had just arrived. While I was there she had a couple of pains, but I made no examination at the time for the reason that I believe a vaginal examination often hastens a labor, and I preferred to have a little delay for reasons of my own. On the other hand, I was satisfied from the history given and from watching the patient during pain that I could safely leave her for a time, especially since I could be easily summoned by telephone if needed.

I returned and made an examination at 7.15. I found the os uteri slightly dilated. There was no "bag of waters." To the best of my judgment I had to deal with a breech presentation in the S. L. P. position. For this diagnosis I was almost as much dependent upon external palpation as upon vaginal examination. After giving some further directions I left, promising to return shortly after 9.

When I again reached the house, at 9.15, I was informed that they had telephoned for me within five minutes, about which time the body was born, but they had been unable to extricate the head.

Mrs. A. was lying upon her back and the child prone between her limbs. I had no difficulty in extracting the head by means of my index hooked over the lower jaw and with the body elevated.

I found the child in a condition of asphyxia pallida. Every muscle was relaxed. There was practically no pulsation in the cord and the heart of the child was only beating about forty times a minute and very feebly.

I immediately wiped out the pharynx of the child,

but was surprised to find it relatively dry. I immediately cut the cord and began artificial respiration by the methods of Schultze and Sylvester, and also by a method which I have long used with good results, but which I have never seen described until recently. It is performed as follows: The child lies supine upon the operator's palms, its head being supported by his right thumb and index. The operator rotates his hands, first elevating the ulnar side, thus permitting the chest to expand and the lungs to fill. Then flexing the child upon itself the air is expelled.

I also tried traction upon the tongue, and several times I passed my finger covered with a handkerchief into the pharynx. I slapped the body, especially over the heart. I used alternately hot and cold water, both in dash and plunge. In spite of all this every muscle remained flaccid. There was not the slightest reflex apparent nor evidence of revival. Not only so, but I could get no evidence that by any of the methods tried any air had entered the lungs. Apparently I had to do with a genuine atelectasis. The lung-cells had perhaps become agglutinated, needing something more than ordinary atmospheric pressure to open them.

I put the child upon a table, holding its head upon my right hand slightly lower than the body. My left hand I laid upon the abdomen, with my fingers on one side and my thumb on the other side of the thorax. I then carefully filled the lungs by air from my own mouth. As soon as the chest was full I compressed it with my left hand. After about half an hour's work the child gasped, and the gasps became more frequent until about 10 o'clock she was breathing. I alternated this method of artificial respiration with the others, and after I had once inflated the lungs I forced a little bloody mucus from the nose by the Schultze method.

I had the child oiled all over with warm lard and then I rubbed her with warm flannels. She frequently stopped breathing, and even with the care taken she was getting cold. At last, however, she was breathing regularly, though rapidly, and the body was warm. There were some coarse mucous râles in the bronchi.

After 1 o'clock the household quieted down for the night. The next morning I was informed that the child had rested well and nursed strongly. At 5 P.M. the baby still seemed to be doing well. She had urinated and defecated. She had nursed several times. There were still the mucous râles. I had the nurse put the baby over her shoulder so that I might more easily listen at the back of the chest. While I was doing so the baby put her fist in her mouth and sucked it strongly.

About 10.30 P.M. the child was lying in her mother's arms for sleep. The mother thought she did not seem natural and aroused the household. When I reached the place half an hour later I found the baby's face very dusky. Pulse and respiration 70, the alæ nasi distending strongly with each inspiration. Temperature taken in the axilla 106.1° F. I made, of course, an unfavorable prognosis, considering the case one of broncho-pneumonia, apparently most severe on the right side. Diagnosis was based upon generally diffused percussion-dulness, with spots of increased resonance and mixed mucous râles. Life lasted until 5 o'clock the next morning. The pulse remained strong until long after the respiration had become feeble and infrequent. From the time I was called the little patient was unable to swallow. She never cried from the time she was born. After death I noticed protruding from the nostrils something similar to cotton in appearance. The nurse informed me that this first became visible about two hours before death. I have never seen a like substance except in cases of diphtheria.

The mother made an uneventful recovery in spite of the severe shock caused by the sudden death of the baby. Thirteen days after the birth of the baby the other child had a sudden and severe attack of laryngitis, which lasted about five days, though it had been preceded by a slight cough which was at first supposed to be pertussis, caught from cousins. I could detect no false membrane in this case, though there were some indications in sound and temperature that it might be membranous. There were cases of diphtheria and scarlatina in that portion of the city, though I knew of no communication with such cases.

In the case of the baby I noticed a peculiar odor to the breath, and at the same time considered the possibility of infection through my breath at the time of resuscitation, though I was in good health.

The case illustrates to me:

1. That inflation by expired air may succeed when other methods fail.

2. That the method is dangerous because of the ease with which mechanical injury may be done in spite of care.

3. That the method may be dangerous because of the possibility of infection.

I do not think that delay in extricating the head from the vaginal canal was the only cause of atelectasis, because:

1. The child's pharynx was clear from mucus. Of course, if the child's face were covered by the posterior wall of the vagina asphyxia might be produced without the inhalation of mucus. In that case, however, as soon as the face was extricated there would be no further obstruction to respiration.

2. Atmospheric pressure alone was not able to open the air-cells of the lungs.

CONJUGAL DIABETES.

BY HORACE Y. EVANS, M.D.,
OF PHILADELPHIA.

THE literature of conjugal glycosuria is deemed sufficiently extensive and reliable to banish the instances of its occurrence from the category of coincidences.

As long as we are without positive knowledge of the pathology of diabetes mellitus we are encouraged in presenting any peculiarity or anomaly that may tend to confirm or disprove some of the many theories suggested as to its cause.

The data of the following cases are given for the same reason that cases of suspected communication of phthisis pulmonalis from husband to wife were reported twenty-five years ago.

The experience of many of us will no doubt agree with the statement of Debove: "Il est probable que la proportion aurait été plus grande si j'avais toujours en soin d'examiner l'urine des deux conjoints."

The apprehension at the present time seems to be that, under some, as yet, unrecognizable circumstances, diabetes mellitus does become contagious.

Especially does the slowly accumulating testimony go to show the possibility of the husband communicating the disease to his wife.

Mr. C., married at forty-six years, glycosuria developed at fifty years, died of broncho-pneumonia at sixty years.

Mrs. C., married at forty years, glycosuria developed at forty-eight years, died of œdema of the lungs at sixty-two years.

Mr. W., married at thirty years, glycosuria developed at sixty years, died of diabetic coma at sixty-eight years.

Mrs. W., married at twenty-eight years, glycosuria developed at sixty-five years, died of diabetic coma at seventy-five years.

These cases presented no symptoms but such as are usual in chronic diabetes.

They were all corpulent people, weighing from 180 to 250 pounds.

None of them were blood-relations.

Heredity was not a factor in any of them.

None were of the Semitic race.

Three of the four were natives of Philadelphia.

One of the four also was a neurotic.

One only was a sumptuous liver, occasionally using alcohol and tobacco.

LARYNGEAL SYPHILIS, WITH REPORT OF A FATAL CASE; AUTOPSY-NOTES.

By A. M. DAVIS, Ph G., M.D.,
PATHOLOGIST TO GERMANTOWN HOSPITAL.

This affection, which is one of the most obscure and most interesting manifestations of general syphilis, affording as it does varied clinical and pathological features, has been claimed by many authorities to be of more common occurrence than is generally supposed. Engelsed[1] saw involvement of the larynx 25 times, among 521 cases, or 4.8 per cent. In 218 cases examined by Willigk, 15.1 per cent. showed laryngeal disease, while in Sir Morrell McKenzie's statistics, taken from 10,000 cases, 308 gave evidence of involvement of this organ, furnishing an average of nearly 32.5 per cent.

The lesions appear wide and varied, consisting at the onset of a simple catarrh or follicular hyperplasia, terminating in either condylomata, gumma, or extensive ulceration, with necrosis and cicatricial formation, either singly or combined, as the case may be.

Virchow thus describes gummy tumors:

"Their beginning consists of little, roundish elevations (on the epiglottis and within the interior of the larynx, either singly or as a conglomerate mass) similar to the follicles of the root of the tongue, but of a softer, more marrow-like consistency, often richly supplied by bloodvessels, and especially surrounded with varicose veins. These nodules ulcerate on their surface, at first forming shallow ulcers (the surface breaking down and being cast off), and gradually penetrate in depth as new portions of tissue are involved in the change. . . . If the ulceration reaches a certain depth, a purulent perichondritis usually becomes associated with it, which is combined with partial necrosis of cartilage, and finally effects the expulsion of the necrotic pieces, with the formation of deep sinuous cavities. It is these deep laryngeal ulcers that bring about the much-dreaded stenoses when they undergo partial or complete cicatrization. The margin of the epiglottis becomes at first infiltrated, then the ary-epiglottidean ligament, followed by the true and false cords."

Norton describes a fatal case from a gumma the size of a pigeon-egg, which was situated in the right epiglottic fold.

The most common period of life at which laryngeal syphilis exists is quoted between the ages of twenty and forty years, but cases have been known of hereditary origin; thus, Isidor Frenkl records the case of an infant, apparently healthy at birth, which developed two months later an acute coryza, with progressive laryngeal dyspnœa. Three weeks after the development of the first symptoms death followed, due to stenosis. The autopsy revealed necrosis of the cricoid and left arytenoid cartilages and syphilis of the liver, all of the other viscera being in an apparently normal condition. Following is the report of a case which occurred during the writer's term as resident physician in the Philadelphia Hospital:

J. T., aged forty-six years. Nativity, Philadelphia. Cause of parents' death unknown. No hereditary disease peculiar to the family. She was always healthy when a child; other than this statement the patient absolutely refused to give her history. Physical examination revealed the following: Well-nourished and corpulent individual, weighing about 200 pounds. The breath-sounds during ordinary respiration were quite audible, inspiration being louder and higher pitched than expiration. While the patient remained quiet dyspnœa was scarcely noticeable, but developed on making any unusual exertion, becoming at that time severe and distressing. Several small, irregular ulcers were noticed on the skin of the abdomen and back, and a rupial sore about three inches in diameter, containing a grayish slough, covered the left frontal prominence, the ulceration extending down to the frontal bone.

The tongue and mucous membranes of the cheeks were covered with mucous patches. Examination of the thoracic and abdominal viscera gave negative results.

The patient was placed on the "mixed treatment," consisting of the bichloride of mercury, gr. $\frac{1}{24}$, with iodide of potassium, grs. 10, three times daily, the patches on the tongue and cheeks having been cauterized with the solid stick of silver nitrate. Ten days later symptoms of ptyalism began to develop, and about the same time the laryngeal dyspnœa increased markedly. Pain was absent, and the temperature remained normal. One month after admission the patient was found cyanosed and unconscious, gasping for breath, death resulting in a few minutes, before tracheotomy could be performed.

The autopsy notes were as follows:

An immense amount of adipose tissue surrounded the abdominal viscera and was contained in the abdominal wall, measuring at a point above the crest of the pubis 7 cm. in thickness.

Larynx: The tongue, which was removed with the larynx, showed the circumvallate papillæ to be enormously distended. Epiglottis and vault of the pharynx apparently normal. The thyroid cartilage on the left

[1] Cited in Virchow and Hirsch's Jahresbericht, 1868, ii. b. d., p. 585.

side was necrosed, the necrotic area extending across the median line to the right and being surrounded by a sloughing ulcer which filled up the entire space below the left cord. The tissues underlying the right and left cords were sensibly swollen, the mucous membrane of both cords being inflamed and infiltrated.

Heart: The muscle was thin and everywhere infiltrated with fat, bands of which could be seen running between the fasciculi, giving the peculiar, striped yellow-red appearance. The mitral valve contained a spicule of calcareous infiltration on the free margin of one of the cusps and another nodule near its base; other valves normal.

Kidneys: Cortex showed two or three depressions, the result of hemorrhagic infarcts which had been partially absorbed; otherwise normal.

Liver: Normal in size and weight. Section revealed evidences of fatty infiltration.

Voluntary muscles: Were soft in consistency and infiltrated with fat.

An examination of the lungs, spleen, stomach, bladder, uterus and appendages, and intestines failed to reveal anything pathological.

The pathological diagnosis was: Syphilitic laryngitis, with fatty infiltration of the voluntary muscles, heart, and liver.

Another case of asphyxia from stenosis due to syphilitic laryngitis occurred during the writer's term of service, in which tracheotomy was successfully performed, the patient dying, however, ten days later from aspiration-pneumonia.

MEDICAL PROGRESS.

Iron not Necessarily a Large Ingredient in Our Food.—Those of the profession who are in the habit of largely prescribing ferruginous tonics will do well to remember that the amount of iron contained in the average daily diet of a man seldom exceeds 10 mgms., and a like amount is represented in the excreta.—DR. STOCKMAN, *Journ. Physiology*, vol. xviii. p. 488.

Bilateral Variation of Temperature.—PULLIN (*Lancet*, No. 3771) reports a fatal case of typhoid fever showing a variation of temperature between the two sides of the mouth throughout the attack, amounting at times to several degrees—the greatest disparity recorded was 3.2°. It was noted that the left side furnished the higher temperature, except on one or two occasions. The thermometer was applied between the teeth and cheek on either side. Due care seems to have been taken in these observations.

Post-mortem Cæsarean Section.—HOFFMANN (*Centralbl. für Gynäkologie*, 1895, No. 50, p. 1319) has reported the case of a woman, aged thirty-six years, who in the eighth month of her fourth pregnancy was suddenly seized with eclampsia, terminating fatally in the course of 2½ hours. Ten minutes after the last inspiration Cæsarean section was undertaken, and a living male child, 15 inches long, delivered. The infant was nourished with the aid of a spoon, but it died at the end of 25 hours in consequence of enfeebled vitality.

Cerebral Surgery.—At the last meeting of the International Congress of Otologists, DR. THOMAS BARR stated (*Journal of Laryngology*, etc., vol. ix. p. 817) that we are now able to reach and deal successfully with the following conditions: 1. Abscess in the cerebrum, especially in the temporo-sphenoidal lobe. 2. Abscess in the cerebellum. 3. Purulent formations at the base of the skull. 4. Infection-thrombosis of the sigmoid sinus.

Who should operate? The question as to who should operate upon these intracranial conditions was presented to the same body, and it was conceded by all that operation belonged appropriately to the province of the pure otologist.

Restoration of Cutaneous Continuity by Epithelial Grafting.—To overcome the disadvantages occasionally experienced in practising the usual methods of skin-grafting, MANGOLDT (*Deutsche medicin. Wochenschrift*, 1895, No. 48, p. 798) proposes a new mode of transplantation. After shaving and disinfecting a suitable portion of the body, preferably the inner or outer surface of the forearm, the skin is made tense and gently scraped down to the papillary layer by means of a sharp razor held at right-angles to the surface. The mixture of blood and epithelium removed is transferred to the previously prepared wound that is to be covered, and there firmly applied with the aid of pressure and a protective dressing. The graft adheres readily, and in the course of a week gives signs of its presence and growth; a new layer of epithelium will usually have formed after the lapse of three or four weeks.

A Contribution to the Statistics of Adenoid Vegetations of the Naso-pharynx.—As the result of an extended clinical study, ARSLAN, of Padua (*Ann. d. Malad. de l'Oreille, du Larynx, etc.*, 1895, No. 12, p. 509), has arrived at the conclusion that adenoid vegetations of the naso-pharynx are of frequent occurrence in Italy. He maintains that heredity and dyscrasic diseases play the principal *rôle* in the etiology; next in importance follow humidity and infectious processes. Operative treatment should, if possible, be concluded at a single sitting. The Moritz Schmidt incision, followed by scraping with the finger, should constitute the procedure of choice. Ethyl bromide is the best anæsthetic for the purpose, and is far superior to chloroform, to ether, and perhaps also to nitrous oxide. In all cases in which the presence of adenoid vegetations in the naso-pharynx is detected the growths should be removed, even if not voluminous. All children should be subjected to a naso-pharyngeal examination before being admitted to public or private schools, to institutions for deaf-mutes, or to other educational institutions.

The Etiology of Multiple Sclerosis.—With the view of clearing up some of the doubt involving the question of the etiology of multiple sclerosis, KRAFFT-EBING (*Wiener klinische Wochenschrift*, 1895, No. 51, p. 895) made a study of 138 cases seen in private and hospital practice. To this end he included in his investigation only cases in which the diagnosis was indisputable; 38 cases were thus excluded. Fifty-eight of the cases were in males, 42 in females. The largest number (44—28 males=16 females) occurred between the ages of twenty-one and thirty years. Among 53 cases (35 males, 18 females), in which an etiologic factor could be

elicited, cold and wet could be considered of causative significance in 40 (30 males, 10 females). These cases fall naturally into two groups: (*a*) Those in which exposure occurred but once, though in intense degree; and (*b*) those in which the exposure was slight but long continued. In the former the symptoms of sclerosis appeared at once, while in the latter they developed insidiously. How cold and wet bring about multiple sclerosis is yet a matter for discussion—whether by lowering the bodily resistance to infection, or by the generation of noxious miasms outside the body, or by inducing metabolic changes leading to autointoxication, or by disturbance of the circulation and the nutrition of the nervous system through an influence upon the vasomotor apparatus.

Familial Myoclonus.—UNVERRICHT (*Dtsch. Zeitschr. f. Nervenheilk.*, 1895, vii, H. 1, 2) reports three cases of the disorder known as myoclonus, which correspond to the cases previously described and justify the recognition of a typical clinical entity. The disorder is manifested by lightning-like contractions, affecting individual muscles of the trunk, face, and extremities. In no case was the face free from movement, but in none also was any movement of the eyeballs observed. The œsophagus, the tongue, the thorax, and the diaphragm were all involved. Although the muscles were symmetrically affected, there was an absence of synchronism in the movements. Muscles acting synergistically were never jerked in common or simultaneously; on the contrary, single muscles or even muscle-bundles were affected. Nor were the movements co-ordinated, as from cortical irritation. The characteristic feature was the absolute arrhythmia. The movements were increased by psychic influences, and seemed to be restrained by the will. They were lessened, but not entirely subdued, by sleep. The affection has been observed in several members of a single family, and complicated by epilepsy. The disorder is to be differentiated from hysteria, chronic progressive chorea, and epilepsy. The movements differ from those of chorea in not involving muscles acting synergistically and influenced individually by the will. This peculiarity suggests the spinal cord as the seat of the pathologic process that acts as a cause. Therapeutically, hyoscine failed, while chloral proved successful —*Centralbl. f. d. medicin. Wissenschaften*, 1895, No. 50, p. 891.

Extensive Suicidal Injury of the Vessels of the Neck, with Recovery.—THOMAS (*British Medical Journal*, No. 1823, p. 1420) has reported the case of a man, sixty-five years old, who, in an attempt at suicide with a penknife, had made a deep wound in the left side of the neck. The sternohyoid and omohyoid muscles were divided; the internal jugular vein was cut through, and its cut ends were collapsed and three-quarters of an inch apart; the common carotid artery was cut into, but not divided; the thryoid cartilage was notched, and the external and anterior jugular veins were severed. Clamp-forceps were immediately applied to the cut vessels and one on each side of the aperture in the common carotid, from which a small spurt of blood, certainly not half a teaspoonful, was jerked out. The left median basilic vein was exposed by an incision and twenty ounces of warm saline solution were slowly perfused, an ordinary glass syringe with a capacity of five ounces, with an india-rubber tubing attached to a canula in the vein, being employed. After seven ounces of fluid had been injected, the man made a short, distinct inspiration; at ten ounces a deeper one (the radial pulse could now be felt beating feebly); at fifteen ounces the breathing became regular and deep; at eighteen ounces the man opened his eyes, but did not appear to be conscious. The clamped vessels were now tied with catgut and the wound cleansed with carbolic-acid lotion and dressed with cyanide-gauze. The man was surrounded by hot-water bottles and the foot of the bed elevated eighteen inches. In the course of an hour the patient had recovered sufficiently to answer in a squeaky voice to his name when called loudly. Improvement proceeded rapidly until the twenty-second day, when violent hemorrhage occurred, preceded a few hours previously by a small trickle, easily controlled by pressure. The wound was at once opened and blood found oozing from the distal extremities of the carotid artery and jugular vein, which were promptly clamped. The common carotid artery was not sound, so that ligatures were applied to the internal and external carotids and to the internal jugular with a small branch entering into it. The patient was greatly collapsed, but quickly rallied, only to suffer renewed hemorrhage from the internal carotid nine days later. This was controlled by pressure with sponges, and a quart of hot water was injected into the rectum. From this time on the patient made a slow recovery, a small sinus in the lower part of the neck disappearing on the removal of a catgut ligature.

THERAPEUTIC NOTES.

Mentholated Oil for Purulent Rhinitis.—FOUGERAY (*Ann. d. Malad. de l'Or., du Lar., du Nez et du Pharynx*, 1895, No. 12, p. 497) has reported a case of acute primary purulent rhinitis in an infant, thirteen months old, due to the staphylococcus albus and staphylococcus aureus, and in which a cure was effected by the use of a 10 per cent. mentholated oil sprayed into the nares and the pharynx five or six times daily.

For the Abdominal Pains of Muco-membranous Enteritis.—

Take of

Menthol	3 grains.
Alcohol, sufficient to dissolve.	
Simple sirup . . .	6 fluidrachms.
Water	3 fluidounces.—Mix.

Dose: Take three or four times in twenty-four hours.
—MATHIEU, *Rev. de Thérap.*

The Treatment of Malarial Cachexia with Splenic Tissue and Bone-marrow.—CRITZMANN (*Presse Médicale*, 1895, No. 68, p. 507) has reported four cases of chronic malarial cachexia presenting enlargement of the spleen, anæmia, and emaciation, successfully treated with splenic tissue and bone-marrow after the usual remedies, quinine, arsenic, hydrotherapy, etc., had failed. He administered daily rather more than an ounce and a half of finely chopped spleen from a young beef, admixed with the yolk of an egg and two drachms and a half of bone-marrow. Improvement soon set in, and in the course of two or three weeks became quite pronounced.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

THE LUNG AS A POINT OF LEAST RESISTANCE.

IN our last issue we discussed the principle which determines the localization of disease and, from the standpoint of the evolutionary pathologist, advanced the theory that morbid action in many instances means simply a reversion to processes which were normal in an early ancestral or embryonic stage of development. In the case of the uterus and mammæ we saw the application of the law that late appearance means early decay.

In the case of the lungs, however, its application will be promptly challenged, first by the bacteriologist, on the ground that tubercle is an "exposure" disease due to aërial spore-infection, and, secondly, by the physiologist with the obvious statement that the lung remains functionally active as long as life continues. But a closer inspection will, we think, show not only that we may claim its applicability here, but also that it explains the actual condition of affairs better than any other hypothesis. Granting for the sake of argument that tubercle is chiefly contracted by aërial infection (although the great current of recent evidence seems steadily setting toward the view that it enters the system *via* the alimentary canal, and, gaining access to the blood- or lymph-stream, is carried to "points of least resistance" all over the body, the glands, the joint-cavities, the "growth-line" of bones, etc., where it settles and breeds), how are we to account for its peculiar site of attack and development in the apices of the lungs? It certainly cannot be upon any mechanical "settling" or "lodging" principle, for if this were the case then the special filters of the inspired air, the turbinated bodies, would be the commonest seat of attack, the narrowed channel and voluminous pouches of the larynx the next, and the bronchi and the air-cells last of all, which is exactly the reverse of the actual susceptibility. Nor would it seem to be due to a subsidence of the bacilli or spores where the air-current is most stagnant, for even such microscopic particles as they are ponderable and subject to the law of gravitation, and would tend most commonly to fall into and accumulate in the even narrower and more isolated recesses of the *lowest* parts of the lung. Another explanation commonly advanced is that on account of the comparative immobility of the first and second ribs and the pressure of the shoulder-girdle, there is less respiratory movement in this part of the lung than in any other, and hence it is a place of physiologic stasis, a *cul-de-sac*. To which it may be answered, first, that while this lack of "pumping-force" might apply to fluids, it does not at all to gases, and that any tendency to imperfect expansion of the apices would be more than overcome by the tendency of air to seek the *highest* point of cavities, of which the familiar distention of the fundus of the stomach is a case in point; and, secondly, that this expansion does actually take place, so that the apex of the lung is *not limited* by the ribs or even by the clavicle, but extends often *above both* into the yielding tissue of the neck, where anyone who has seen it rising and falling at the bottom of the chasm left after the removal of tubercular cervical glands will be inclined to regard it as really one of the most expansile parts of the organ instead of the least so. The most recent theory is that of terminal blood-stasis, on account of the absence of valves in the pulmonary veins and certain peculiarities in the connections of the veins of the upper part of the lung. But this is opposed by the facts, first, that the apex is really less remote from the source of supply in the roots of the lung than the base, and, secondly, that all pulmonary congestions which are confessedly static in their origin occur at the lowest points,

the base in the upright and the posterior border in the recumbent position.

When, however, we regard the apex of the lung from a comparative and developmental standpoint we find it to be the shrivelling and receding remnant of a cervical extension of the respiratory cavity, whose existence is indicated by the frequent occurrence of one or more cervical ribs, and whose disappearance is part of the general recession of the original body-cavity (cœlom) or pleuro-peritoneal sac. Thus its peculiar susceptibility to disease becomes explicable on the law of the proneness to decay of "senile" or atrophying organs.

As Wiedersheim[1] remarks, "these phenomena (the structural changes of the first rib and apex) should be regarded as degenerative," and the apex falls into the same pathogenic class with the appendix vermiformis.

And not only does this view account for the marked proclivity of disease for a site so inaccessible and otherwise highly improbable as the apex, but it also appears to account for its preference for the right apex, which is in the proportion of three to two. As is well known, upon the right side of the chest we find three lobes and upon the left only two, and as the uppermost right lobe is supplied by an eparterial bronchus, which is not represented upon the left side at all, it is generally believed by morphologists that the superior or special lobe of the right lung is the remains of an eparterial lobe, which was also originally present (but has now completely disappeared) upon the left side, as is the case in many mammals (horse, elephant, seal), and in rare instances as a reversion in the human subject (Dalla Rosa, Bohls). And the apex which is formed by this atrophying lobe is nearly twice as frequently the site of tubercular disease as its fellow of the opposite side. All these may of course be nothing more than coincidences, but to the comparative pathologist they are highly suggestive ones, and of sufficient interest even to clinicians to warrant high expectations of further developments in this field of research.

[1] Structure of Man, p. 179.

PHYSIOGNOMY OF CRIME.

IT is rather startling to read that crime is on such an increase in this country that it is five times more common to-day than it was in the year 1850; yet such is the fact, according to the figures given by General Brinkerhoff, President of the National Prison Congress. These figures are as follows:

Year.	Prisoners.	Ratio to population.
1850	6,737	1 in 3442
1860	19,086	1 " 1647
1870	32,901	1 " 1171
1880	58,609	1 " 855
1890	82,329	1 " 757

This rapid increase suggests either that our whole population will soon be in jail if something is not done to prevent it, or that these statistics need explanation and correction. That there is some error, or at least some unknown factors at work to give this appearance of rapid decline in the public morality of this country, we cannot doubt; but what it is we cannot suggest. It can scarcely be due to increased efficacy of our police and judicial systems, by reason of which more offenders are tried and convicted; it is quite as likely to be due to the increased laxity of our tribunals and pardoning boards, by reason of which more convicts are sentenced a second and a third time, and so go to swell the prison population.

It is very evident, however, that these figures, even if subject to revision, are significant of something radically wrong in our civilization. They show only too plainly that our antiquated criminal laws and law-courts are not meeting the demands of the country in suppressing and controlling crime. These laws and procedures, in other words, are not founded on *scientific* principles; they have not come into line with the advances made in other departments of human knowledge and activity. This is seen at once if comparison is made with some of these other departments. Let us take, for instance, that of public hygiene, which has to do with the conditions and general control of diseases and disease-production. What would be thought if the increase of disease, as shown, for instance, in the mortality-rate, had been at a rate comparable with this increase of crime?

It is not to be wondered at that scientists are beginning to protest against a system of trial and administration which is responsible, even if only in part, for such results. One of the most prominent of the specialists who have attempted to place criminal anthropology upon a scientific basis is Professor Cæsar Lombroso, a translation of one of

whose recent works is now before us.[1] As a rational attempt to master this difficult subject by applying to it a scientific method we shall refer briefly to Lombroso's work and submit it to a necessarily condensed criticism.

In the first place, we may say that we have been much impressed with some of the facts stated by Mr. Morrison in his introduction. He shows conclusively, from the statistics of the New York State Reformatory, that conditions of environment have much to do with the production of criminals; 52 per cent. of juvenile delinquents came from homes which were positively bad, and only about 7 per cent. from homes which were positively good. Again, 41 per cent. left home before or soon after reaching the age of fourteen, while only 1 per cent. were surrounded by wholesome influences at the time of their lapse into crime. This moral aspect of the subject strikes us as of great significance in an introduction to a book which, like Lombroso's, deals almost exclusively with the mechanical and physical aspects of the criminal. Mr. Morrison himself does not point out this latent inconsistency. In all these juvenile criminals we cannot help but think that their vicious environments had more to do with their fall than had the shapes of their skulls and their other purely somatic characteristics. Even their mental and moral traits may have been formed as much by example as by heredity.

It may surprise some to know that Lombroso does not attach first importance to cranial anthropometry. He says distinctly that variations in measurement between the normal and the abnormal cranium are so small as to defy all but the most minute research. He attaches greater importance to the anatomico-pathological anomalies of the female offender, and gives a list of them; a list which only experts can consult and use with profit. He does not ignore general anthropometry, however, but gives it considerable importance; in fact, it occupies large space in his book. In respect to the data collected by Lombroso in these various fields, and which he offers in a startling array of figures, we frankly confess that we should not like to give a hasty and rash opinion. The impression made upon us is that Lombroso's work represents a method and a beginning, but that it may be over-hasty yet for even the most expert to draw from it conclusions which are to be regarded as applicable in the present state of society and criminal law.

Among the anomalies described and classified by Lombroso are those of the head, face, ears, and teeth. The list includes such topics as asymmetry, prognathism, virile and Mongolian physiognomy, peculiarities in the hair, and tattooing. These and innumerable others are submitted to a statistical study, so that the book in parts is much overloaded with figures, which may add to its scientific value, but which detract somewhat from its interest. On the debatable ground of tattooing, where Lombroso has been freely criticised, we do not think that he makes out much of a case for the female offender. The most curious induction drawn by him is that in the simplicity of her tattooing, as compared with the male, the female offender furnishes an example of atavism, since she tends to revert to the practice of the women of savage tribes, who notoriously are less tattooed than the men.

In some parts of his book Lombroso abandons his more strictly mechanical work and attempts to give the mental traits of the female offender, especially in crimes of passion. As a psychological study this attempt does not seem to us to establish satisfactorily anything distinctive. The passions and crimes of these offenders are strictly conventional, and only lead to the conclusion that those who displayed them were in a general way without moral control; *i. e.*, that they were criminal.

The chapter on hysterical offenders is to us the least satisfactory in the book. It is not a scientific study of hysteria according to the approved modern ideas of that disease. It is, in fact, exceedingly superficial and uncritical. Lombroso, following the bad example of Legrand du Saulle, hopelessly confuses hysteria with all forms of moral depravity and degeneracy. He brings an indiscriminate charge against hysteria of producing liars, thieves, and murderesses, but the symptoms and mental traits that he enumerates are almost without exception not those of the great neurosis. We emphatically dissent from the method followed and the results obtained in this chapter.

The fact that true hysteria is not common in, much less identical with, criminality is curiously shown by Lombroso in a study of the visual fields of female offenders. These criminals present rather frequently scotomata and a rather characteristic peripheral irregularity of the visual fields (marked,

[1] The Female Offender. By Professor Cæsar Lombroso and William Ferrero. With an Introduction by W. Douglas Morrison. New York: D. Appleton & Co.

for instance, by great peripheral depressions). But the author distinctly says that the absence of the special visual characteristics of hysteria proves that the moral and functional anomalies of criminals are not due to hysteria. This is in strong contrast with his other statements about hysteria, to which we have just taken exception. His chapter on the acuteness of all the special senses in criminals is a very close study.

Lombroso also devotes special chapters to the characteristics of the born criminal and the occasional criminal. We have not space to present these sketches, but we may say that their outlines are perhaps rather misty for the practical purposes of criminal jurisprudence as this is at present practised.

On the whole, Lombroso's work, as exhibited in this book, presents us with a method rather than with fully accomplished results. The value of this method must yet be tested by experience founded upon work by more than one man and in a wider field, and by the verdict of a yet somewhat remote future. We are impressed, however, with the importance of this method, and with the hope, even belief, that it will yet do much to solve some of the grave sociological questions that have to do with the production and the control of crime.

We ought not to omit to mention, perhaps, that Lombroso has exhibited to us, in this book, photographs of the skull of Charlotte Corday. The readers and admirers of Lamartine[1] will perhaps learn with dismay that this "Angel of Assassination" has presented to modern science a large number of anatomico-pathological anomalies in her cranium!

ECHOES AND NEWS.

PROF. V. BRUNER, Director of the Anatomical Institute at Rostock, is dead.

DR. J. M. DACOSTA has been re-elected President of the College of Physicians of Philadelphia.

DR. LEONARD PEARSON, of Philadelphia, has been appointed Pennsylvania State Veterinarian.

DR. AUGUST BIER has been elected Extraordinary Professor of Surgery in the University of Kiel.

DR. SAMUEL G. DIXON has been elected President of the Philadelphia Academy of Natural Sciences.

DR. WILLIAM E. HUGHES, of Philadelphia, has been elected President of the Delaware Valley Ornithological Club.

PROF. WICHERKIEWICZ, of Posen, has been elected to the Chair of Ophthalmology in the University of Cracow.

DR. WILLIAM PEPPER, of Philadelphia, has been elected one of the Vice-Presidents of the American Philosophical Society.

PROF. P. EHRLICH has succeeded to the Chair of Special Pathology and Therapy in the University of Berlin, formerly occupied by the late Prof. A. Hirsh.

PROF. V. HÜFNER, of Tübingen, has been called to the Chair of Physiologic Chemistry in the University of Strassburg, rendered vacant by the death of the late Hoppe-Seyler.

DR. LUDWIG RÜTIMEYER, Professor of Comparative Anatomy at the University of Basle, and well known for his paleontologic investigations, died recently at the age of seventy-one years.

PROF. BRAUN, of Königsberg, has been called to the Chair of Surgery in the University of Göttingen, in succession to König, who was recently made a member of the faculty of the University of Berlin.

THE Section on Surgery of the New York Academy of Medicine at its regular meeting last Monday night elected Dr. B. Farquhar Curtis, of 307 Madison Avenue, Chairman, and Dr. John B Walker, of 33 East Thirty-third Street, Secretary.

THE UTILITY OF STATE MEDICAL EXAMINATIONS is again demonstrated by the announcement that the Pennsylvania State Board of Medical Examiners recently rejected 22 out of 76 applicants for a licence to practise medicine in that State.

THERE has recently been resurrected in the document-rooms of the Senate in Washington an old claim of Issachor Zacharie, a former chiropodist of New York, against the Government, amounting to $45,000, for treating corns and bunions of soldiers in the War of the Rebellion.

THE THIRD INTERNATIONAL CONGRESS FOR PSYCHOLOGY will be held at Munich, from August 4 to 7, 1896. The following subjects will receive discussion: Psychophysiology, Psychology of the Normal Individual, Psychopathology, Comparative Psychology. The official languages will be German, French, English, and Italian.

DR. CONAN DOYLE pleads the American view of the Venezuelan dispute. He exposes the faults and arrogance of the English Yankee-haters, and proposes that an Anglo-American Society be started in London, with branches throughout the empire, with a view to promoting good feeling and furnishing the English with the American side of questions that may arise, and *vice versa*.

PROF. RUDOLF LEUCKART, the distinguished zoölogist, celebrated the fiftieth anniversary of his accession to the

[1] See his sketch of Charlotte Corday in his "History of the Girondists."

doctorate on December 13th. In 1850, at the age of twenty-eight years, he was made Extraordinary Professor of Zoölogy at Giessen, and in 1885 Ordinary Professor, and also Professor of Comparative Anatomy. Since 1875 he has been Professor of Zoölogy and Zootomy at Leipsic.

DR. GEORGE DOCK, at present Professor of Practice of Medicine and Pathology in the University of Michigan, Ann Arbor, has been elected Professor of Pathology and Bacteriology in the Jefferson Medical College, Philadelphia. Formerly he held the Chair of Pathology in the University of Texas, at Galveston. Though still a young man, he has a reputation as a pathologist and as an original investigator in bacteriology.

THE senior officers of the service have submitted a bill for Secretary Herbert's approval reorganizing the personnel of the Navy. In the Medical Department this contemplates increasing the number of assistant surgeons to fifty, with the title of junior surgeon and the rank of junior lieutenant. Passed assistant surgeons are to be known as surgeons, while those now in the grade of surgeons are to be staff surgeons.

THE Commissioners of Charities have appointed M. J. Rickert Deputy Warden of Bellevue Hospital. The position is a new one, created by Mayor Strong's new Board of Charities. Mr. Rickert is forty-five years old, and has been connected with Bellevue for twenty-five years. He passed the best civil-service examination in a contest with twenty-five applicants for the position. The salary of the Deputy Warden is $1200 a year.

AT the request of Dr. Landon Carter Gray we warn the profession against a man who is canvassing among physicians of New York, representing himself as connected with the American Union Life Insurance Company, stating that Dr. Gray is the Medical Director, and soliciting them to apply for the position of Medical Examiner, at the same time asking from each a fee of $3. He is an impostor in every particular and the profession should beware.

A NEW lunacy law has been prepared by Assemblyman Horton, of Wayne County, who will introduce at once to the New York Legislature a bill relating to the examination of alleged lunatics prior to being pronounced of unsound mind. The bill provides that none but State insanity experts may examine persons whose sanity is brought into question; that the experts must form their judgment solely from the examination and not from testimony, and that the experts must be strangers to the persons examined.

MRS. CATHARINE HATCH died on January 1st at her home, No. 102 West Thirty-fourth Street, of cancer. Her case became famous some months ago, when Dr. Edward W. Burnette developed a cancer while treating her, from which he subsequently died. Although the secular press jumped to the conclusion that this case demonstrated the contagiousness of cancer by inoculation of the cancer-cell or germ, it has not been accepted as such by the best medical authorities. Mrs. Hatch, it was alleged, had contracted the disease by using a speaking-tube previously used by an infected person, but this was never proved, and she declared that the disease with her was hereditary.

THE INFLUENCE OF THE ANTITOXIN UPON THE MORTALITY FROM DIPHTHERIA IN FRANCE.—At a recent meeting of the Paris Academy of Medicine MONOD (*Médecine Moderne*, 1895, No. 101, p. 783) presented statistics demonstrating the influence upon the mortality from diphtheria in France exerted by the antitoxin since its employment from November, 1894. The following figures represent the number of deaths from diphtheria during the first six months in eight years in 108 French cities having a population of more than 20,000:

	1888–94. Average.	1895. Average.
January	469	205
February	466	187
March	499	155
April	442	160
May	417	113
June	333	84

THE success of a young physician in obtaining the position of assistant in one of our State Asylums evidently excited the cupidity of an obscure but aspiring M.D., and elicited the following unique communication to him:

DECEMBER 13, 1895.

DEAR DOCTOR: I see by the papers you have been appointed as junior physician to ——— Asylum. I am reading for examination some as similar position you hold. Please give me some points as to preliminary qualifications, etc. I will pay you for your trouble if you give me points that will help me Give the branches that counts and the per cent.

I am 35, have had 10 years general practice, 2 private. Habits good, chew some tobacco, can give good ref. as to character, etc.

If you know or have your question you can give me a good idea of what I ask.

Your respectfully, * * * *

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PUBLIC HEALTH.

Stated Meeting, January 10, 1896.

HENRY DWIGHT CHAPIN, M.D., CHAIRMAN.

THE MILK-SUPPLY OF NEW YORK CITY.

DR. GEORGE B. FOWLER, Health Commissioner, presented certain charts prepared from the records of the Board of Health, showing some of the more prominent facts connected with the present supply of milk to this city. He said that on an average there were brought daily into the city 19,164 cans of milk, each holding 40 quarts, and that 78.8 per cent. of this large quantity came from New York State alone. The practical bear-

ing of this fact was evident when one considered the need of certain legislation regarding the control of the milk-supply. At present the State Board of Health had an insignificant sum of money at its disposal with which to pay salaries and reimburse owners of cattle when these were slaughtered to prevent the spread of disease. They had only five inspectors for the whole State. Over 6500 persons deal in milk in this city. The Health Department has made 72,036 inspections of milk during the year, has investigated 106 complaints from citizens, has arrested 408 persons for selling impure milk, and has been the means of collecting over twelve thousand dollars in fines from those brought to trial.

Dr. Edward W. Martin described some of the methods employed for preventing the sale of adulterated milk in the city. He said that for convenience the city was divided into six inspection-districts, corresponding to the judicial districts. When the inspector found by testing milk with the lactometer that it was apparently decidedly below the standard, he made careful notes of his observations, and prepared two sealed samples of milk. One of these was sent to the department-chemist for analysis, the other was delivered to the milk-dealer, so that the latter could, if he so desired, have it analyzed independently of the Health Board. If the analysis and other facts recorded in a given case seemed to justify the arrest of the dealer, this was the next step taken. A careful record of such arrests was kept, and it was interesting to note that in the case of one milk-dealer in New York City there had been, from 1887 to 1893, six arrests made, and his total fines amounted to one thousand dollars. Notwithstanding this extraordinary record, the speaker said, this man was still in the business. About 99 per cent. of all the adulterations of milk investigated proved to be either the addition of water or the removal of cream.

Dr. Ernest J. Lederle spoke of the methods employed in the chemical analysis of milk. He said that at the very outset it was most important to observe certain precautions, otherwise it would not be possible to obtain for analysis a fair sample of the milk. The first precaution was to see that the milk was not acid, for if it were there would be a certain amount of separation of the casein. The next most important point to observe was regarding the churning of the milk. If it had been churned, the fat-globules would be separated, thus preventing one from securing a fair sample for analysis. The milk in the sample-bottle should be mixed thoroughly, but this agitation must be very gentle. Experience has shown that this mixing could be best accomplished by gently inverting the bottle ten times. Where it was only required to determine the total solids, 5 c.c. of the milk were placed in a small dish made of lead and tin, and evaporated to dryness over a water-bath, observing the usual precautions for securing perfect dryness of the residue before weighing. By weighing the dish both before putting in it the sample of milk and after this had been reduced to a dry residue, it was easy to compute the weight of the total solids. This should represent about 12 per cent. The total solids were divided into two groups—those consisting of fat and those not fat. The latter included the casein, albumin, milk-sugar, and salts. If it were required to determine the amount of ash, then a platinum dish must be used, and the residue ignited at a low red-heat. The quantity of ash is quite constant, being about 75 per cent. The determination of the amount of salts indicates whether or not the milk has been adulterated by the addition of water. If the addition of an acid to the ash causes effervescence, it is evident that some carbonate has been added as an adulteration to the milk.

The amount of butter-fat was determined by a rather more difficult process. A strip of filter-paper, 22 by 2 inches, especially prepared for this purpose so as to be free from fat, is rolled up into a small cylinder and made to imbibe the sample of milk. In this way the five grammes of milk are spread over a very large surface. The cylinder of paper is next placed in a sort of distilling apparatus, called an "extraction-apparatus," where it is subjected to the action of ether until all the fat has been extracted from the bibulous paper. This ethereal solution of fat is next evaporated, and on weighing the residue one obtains the quantity of fat. The law here requires that milk shall contain only 3 5 to 4 per cent. of butter-fat, but this is a direct invitation to adulteration. On an average, the milk coming into New York City contains about 4 per cent. of butter-fat, and the law should require this amount.

The speaker next described several of the more simple tests for milk. He first described the lactometer. This instrument, which is a form of hydrometer, is graduated into one hundred equal parts between the zero and 100 on the scale, so that each division represents 1 per cent. To use it it should be very gently immersed into the sample of milk contained in a suitable cylinder, care being taken not to splash the milk up on to the stem of the instrument. Unless the milk is at a temperature of 60° F., the temperature at which the lactometer is graduated, a correction must be made for the temperature. If the instrument should float in the milk at 90°, it would indicate that the sample contained an added ten parts of water. As cream is lighter than milk, it was evident that the removal of the cream raised the specific gravity of the milk, and thus made it yield a higher reading on the lactometer. From this some observers had been led to state that the lactometer was an entirely unreliable instrument, as the instrument might stand at the same point in two samples, one of pure, rich milk, and the other a sample adulterated by removing the cream and adding water. But it should be remembered that the milk-inspector is expected to make use of judgment and experience, and if this were done, there was not the slightest danger of making any mistake. For example, when lifting the lactometer out of a sample of rich milk, one would notice that the stem of the instrument was greasy and that the milk clung to it, whereas if the milk were of poor quality this greasiness would not be seen, and the milk would run off the stem very much as water would do. If, therefore, the lactometer read below 100 at 60° F., the milk was undoubtedly impure; if, on the other hand, the reading was above this point, the inspector must use his judgment and experience in passing on the milk.

The amount of cream could, of course, be roughly determined by allowing it to rise to the surface of a sample of milk contained in a simple graduated tube. It could be quite accurately determined by an instrument called the lactoscope. This is constructed

on the principle that the richer the milk the more water must be added to it in order that it shall become sufficiently translucent to admit of reading through it certain black lines on the inner cylinder of the instrument. A practised observer would soon learn his personal equation, and would not then make an error of more than 25 per cent. in the use of this instrument. Another very quick and quite reliable method of estimating the percentage of butter-fat was by means of a centrifugal machine. With this the error should never exceed 0.5 per cent.

Dr. Rowland G. Freeman then read a short paper on the

SIGNIFICANCE OF MICRO-ORGANISMS IN MILK.

He said that the non-pathogenic micro-organisms were for the most part derived from the dust of the building in which the milk is handled, from the dirt on the cow, etc. It was not improbable that some of these micro-organisms now classed as non-pathogenic were concerned in the production of diarrhœa in children, and they certainly caused souring of the milk; but it was most important to remember that the same loose dairy methods that were responsible for the introduction of the non-pathogenic bacteria were also the cause of the contamination of the milk with the pathogenic forms. These micro-organisms could be detected by staining, by culture, by inoculation into animals, and also by their disastrous effects on the consumers. Undoubtedly many epidemics of typhoid fever, diphtheria, and other infectious diseases have been caused by such impure milk, but there were many technical difficulties in the way of demonstrating the presence in milk of these pathogenic bacteria. The speaker said that probably 7 per cent. of all the cattle in New York State were tubercular, and in our city milk small numbers of tubercle bacilli were frequently present. The tuberculin-test was a most delicate one for tubercular disease, and by its use, in conjunction with wise legislation, we might hope in the future for a better milk-supply.

Dr. Henry M. Coit, of Newark, N. J., the originator of the plan of "certifying milk," gave a short account of how he had come to establish this practice, and what results had been secured. After describing the obstacles he had had to encounter during two years of effort to secure a better milk-supply for cities, he said that it had finally occurred to him that by interesting the medical profession the matter might be taken into their own hands. With a committee of seven or eight representative physicians in Essex County the work had been begun, and after considerable search they had found a dairyman who lived up to the terms of a very stringent contract. Under this contract several experts were employed by the committee and paid by the dairyman, and when they were satisfied that the provisions of the contract were fulfilled they were empowered to certify to the character of the milk-supply. The physicians on the committee were not allowed to have any financial interest in the work. The dairyman who had met with the approval had found in the course of the two years in which this plan had been tried that his daily output of milk had increased from 800 quarts to over 2000 quarts, so that the system could be considered a commercial success. It had also been the means of stimulating neighboring dairymen to increased efforts to improve their product. By proper supervision at the dairy it had been possible to secure a milk of uniform nutritive value, and other important information regarding the effect of different feeding of the cows on the quality of the milk had been secured. The committee had not been able to give the bacteriological side of this question as yet much consideration, although in certain special experiments carried on during the summer it had been found possible to reduce the number of micro-organisms to less than 3400 per cubic centimetre. Dr. Snow, of Buffalo, had already introduced this system of certifying milk into that city.

REVIEWS.

Electro therapeutical Practice. A Ready Reference Guide for Physicians in the Use of Electricity. By Charles S. Neiswunger, Ph.G., author of *Suggestions in Electro-therapeutics;* Professor of Electro-physics, Post-graduate Medical School of Chicago. 128 illustrations. Chicago, 1895.

This little work of eighty pages records the *modus operandi* in the treatment electrically of upward of one hundred and fifty diseased states which vary widely in their character. The treatment of abortion, asthma, chancroids, corns, epilepsy, locomotor ataxia, carcinoma, suppurating wounds, and a number of other conditions is detailed. In the treatment of such conditions no one save the most enthusiastic electro-therapeutist would expect material benefit from the use of electric currents.

The book would appear to be misleading to the practitioner of medicine whose experience with electro-therapeutics has been limited. It cannot be said that the object of the book, "as an aid to the more rational use of electricity in the medical profession," is entirely fulfilled.

The Theory and Practice of Counter-irritation. By H. Cameron Gillies, M.D., London. New York: MacMillan & Company, 1895.

A careful and philosophic study of therapeutic methods concerning which our empiric knowledge outruns our understanding is to be found in the book before us. The author has with considerable care collated from his own experience and from reading the various conditions in which counter-irritation is useful, and has shown its limitations and its applications. The introductory historic chapters are interesting and suggestive. The general principles are clearly set forth. The author believes that the term "counter-irritation" itself is a misnomer, and argues that whatever good comes from the use of external irritants is because they stimulate the activity of the tissues of the part to which they are applied, accelerate the blood supply, and increase nutrition or repair. The defect in this proposition is that it fails to explain why blistering the chest, for example, should be more useful in pleurisy than blistering the heel. There is here, certainly, no such direct connection between the tissues to which the blister is applied and the structure upon which the remedial influence is exerted, as would be required by the author's theory.

TWENTIETH CENTURY PRACTICE. AN INTERNATIONAL ENCYCLOPEDIA OF MODERN MEDICAL SCIENCE. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D. In twenty volumes. Volume IV. Diseases of the Vascular System and Thyroid Gland. 8vo., pp. 841. New York: William Wood & Co., 1895.

THE fourth volume of this great undertaking contains contributions by only four authors. The first is by Dr. James T. Whitaker, and deals with Diseases of the Heart and Pericardium, occupying altogether 454 pages. In this most elaborate monograph, covering all the varied phases of the subjects treated of, has been incorporated a vast mass of facts, whose value, it is to be regretted, is impaired by looseness of expression, unattractiveness of style, unnecessary verbiage, indiscriminate arrangement, and a failure to digest adequately the data presented. The second article is on Diseases of the Bloodvessels, and has been ably written by Dr. A. E. Sansom. It occupies 184 pages, and is characterized by the care and precision for which this well-known clinician is noted. Diseases of the Lymphatic Vessels are quite fully discussed in 45 pages by Dr. Bertrand Dawson, and a liberal bibliography is given. Diseases of the Thyroid Gland, including Myxœdema, Cretinism, Exophthalmic Goitre, Goitre, Malignant Disease, Thyroiditis, Tuberculosis, Hydatid Disease, Syphilis, and Actinomycosis are admirably presented within 131 pages by Dr. George R. Murray, who was the first to use systematically thyroid gland in the treatment of myxœdema, and thus comes peculiarly well equipped for the performance of his task. An extensive bibliographic table will be useful to those who may care to study these subjects independently. Reference is facilitated by an index of 18 pages. The book makes a good appearance, being well printed in clear type on paper of good body, and being well bound.

LA METHOD BROWN-SÉQUARD. TRAITÉ D'HISTOTHÉRAPIE. LA THÉRAPEUTIQUE DES TISSUS. COMPENDIUM DES MÉDICATIONS PAR LES EXTRAITS D'ORGANES ANIMAUX. Par M. BRA. Paris, 1895.

UNDER this array of titles Dr. Bra presents the history and literature of organotherapeutics. Introductory letters by Constantin Paul, Mendel, Ewald, Bruns, Emminghaus, and Byrom Bramwell precede the author's own introduction. All of these authors, though commending the general plan and purpose of the work, are noticeably guarded in their support of organotherapeutics, with exception of the thyroid treatment. Undoubtedly this is the present attitude of the profession to the whole question, but not the less on this account is the work before us interesting and instructive.

Written by one who has been from the first (1889) a pupil and disciple of Brown-Séquard, we are not surprised to find a degree of reliance in testicular fluid as a therapeutic agent accorded by few, and certainly not established by the evidence at hand. The author presents at great length (150 pages) the entire literature of this subject, good and bad, scientific and unscientific. The subsequent chapters on cerebral, thyroid, cardiac, pancreatic, hepatic, suprarenal, muscular, renal, pulmonary, splenic, medullary, and lymphatic therapeutics are equally full and comprehensive.

As a compendium of the literature of these subjects, the work is most admirable; but there is not, as there cannot be, any evidence of definite system, and the mass of material is presented without the coherency that would carry conviction. We end as we began on taking up the book with the feeling that the accumulated evidence will not permit a doubt of the value of the thyroid treatment, and that, so far as the other extracts are concerned, there is a plentiful lack of crucial demonstration.

As an almost cyclopedic presentation of the literature this book may be warmly recommended. and it will be found most useful for the many details of methods of preparation and administration of the remedies with which it deals.

GUY'S HOSPITAL REPORTS. Edited by E. C. PERRY, M.A., M.D., and W. H. A. JACOBSON, M.A., M.Ch. Vol. LI., being vol. XXXVI. of the third series. 8vo., pp. 272. London: J. & A. Churchill, 1895.

WE have learned to look forward with expectant interest to the annual publication of *Guy's Hospital Reports*, with the confident feeling that the year will not have passed without yielding evidences of advance in medical science and art; and this year's *Reports* is no exception to the rule. The present volume contains eleven original articles, all of which are of a high order and some of which are especially noteworthy. Hale White and Channing Pearce contribute an article on Empyema Following Lobar Pneumonia, to which they append reports of twenty-six cases. L. A. Dunn describes a unique Case of Multiple Atrophying Sarcomata of the Head and Neck. John Fawcett records the details of an investigation showing that urine containing piperazin in solution has no solvent effect upon uric-acid calculi; that piperazin fails to relieve the pain of gout and to increase uric-acid elimination; and that it has little or no effect when given to birds in whom uric-acid deposits have been produced by injections of potassium chromate. F. Newland-Pedley discusses the Treatment of Suppuration of the Maxillary Antrum, especially with Regard to the Use of a Permanent Opening in Obstinate Cases; and also the Treatment of Congenital Cleft Palate. Theodore Fisher furnishes a paper on Hypertrophy of the Heart without Gross Organic Lesion. G. Bellingham Smith concludes from a study of forty-eight cases of amputation in senile gangrene that this morbid condition is due to a diseased state of the arteries; that when gangrene is confined to the toes the treatment should be expectant and antiseptic; that picking and cutting away of dead structure close to the affected area, as well as amputation, are to be avoided, on account of the liability of reinfection; that when gangrene has reached the dorsal or plantar surface of the foot, a high amputation is indicated—preferably through or above the knee. F. M. Turner is responsible for an interesting communication on Scarlatinal Nephritis and its Varieties. J. Frederick W. Silk undertakes to show that a combination of nitrous oxide and ether forms a most valuable addition to the list of available methods of producing anæsthesia. P. H. Pye-Smith reports an interesting Case of Bilateral Paralysis of the Facial and Auditory Nerves, and cites two additional instances of similar kind. The work is further embellished by a number of woodcuts and five plates.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, JANUARY 25, 1896. No. 4.

ORIGINAL ARTICLES.

MODERN GASTROSTOMY, WITH REPORT OF A CASE.

BY THOMAS S. K. MORTON, M.D.,

PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC; CONSULTING SURGEON, PHILADELPHIA DISPENSARY; OUT-PATIENT SURGEON, PENNSYLVANIA HOSPITAL; ASSISTANT SURGEON, ORTHOPÆDIC HOSPITAL.

AT this time the methods of forming a gastric fistule by simply incising the abdominal wall over the stomach and suturing the viscus to the wound-margins must be considered obsolete. The surgeon is not justified in subjecting a patient to the horrors of subsequent leakage of the stomach-contents which such methods almost of necessity involve, so that the state of the sufferer after operation may be worse—owing to excoriation and uncleanliness—than that preceding its performance. Certainly such procedures should be relegated to the list of last resorts, only to be suggested when actual starvation is in progress, the œsophagus is impermeable to fluids, and other operations are impossible.

On the other hand, we have now available two, if not three, methods of performing gastrostomy, in which most of the disadvantages of the older operations are obviated, which can be strongly urged at very early stages of œsophageal stenosis, and can be expected to add enormously to the patient's comfort and welfare.

These are the operations proposed respectively by von Hacker,[1] of Vienna (1886); Witzel[2] (1891); and Ssabanejew,[3] of Odessa (1890). The latter method was apparently devised and practised quite independently by R. Frank,[4] of Vienna, in 1892, and should in justice be denoted, as in the present communication, by the compound name of both of these surgeons. To these methods may perhaps in the future be added the procedure advocated by Hahn[5] (1887). We may dispose of this at once in a few words. It consists of making a straight incision (Fenger's) one or two fingers' breadth beneath and parallel with the left costal border external to the rectus muscle. A small opening is made in the peritoneum through which a finger is thrust up to the eighth intercostal space and cut down upon by a second incision from above. A forceps is thrust through this second cut and the stomach grasped and drawn out far enough to be fastened to the skin-margins between the cartilages. Necrosis of the ninth rib has been noted three times subsequent to this operation, so that, because of this and other feared complications and the introduction of more promising methods, it has not found favor, although its author has been pleased with the results and claims that a sphincteric action of the ribs prevents regurgitation.

The von Hacker method, in brief, requires a vertical incision over the left rectus muscle, blunt dissection of that muscle and of the transversalis in the direction of their fibres, small incision of peritoneum, the stomach grasped as near the fundus as possible and drawn a short distance through the wound by slings of silk or silkworm-gut, fixation of stomach to peritoneum on all sides, sutures at upper and lower angles of the wound embracing the whole abdominal wall and outer coats of stomach, and, finally, tamponade of the middle, unsutured portion of the parietal incision. Two or three days later the stomach is incised in the direction of its vessels and a large tube inserted for feeding. The average result of this operation is very fair, but there is great uncertainty that regurgitation will be prevented, although a sphincter-like action of the separated muscle usually prevents leakage around the tube. It has the advantage of ease and rapidity of execution. Its field is limited largely to desperate cases in which these elements are essential, to certain conditions where ready access for subsequent instrumentation of the œsophagus from below is desirable, and where complications may prohibit or render undesirable the two other operations which are to be described.

Albert and Kocher[1] have modified the von Hacker operation by drawing a cone of stomach through the rectus, suturing its base to the parietal peritoneum, and then carrying its apex beneath a bridge of skin to just below the costal margin, where it is brought out, incised, and the fistule-edges united with the lips of the small wound which transmits it. The functional results are said to be excellent.

The von Hacker operation is distinctly contra-indicated in malignant strictures, where the patient's condition justifies either of the following methods:

Witzel's procedure is unquestionably the most

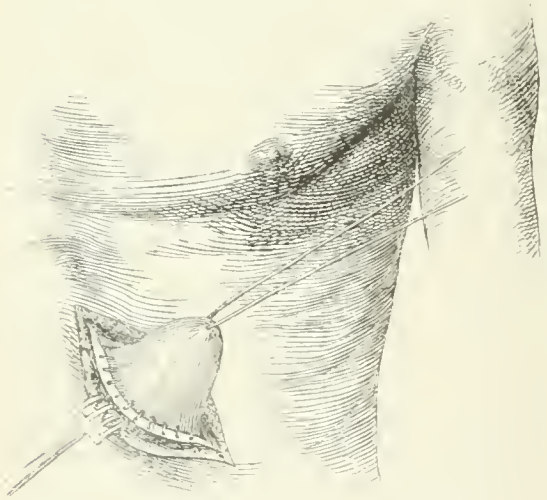
popular of the modern gastrostomy operations. It has the advantages of absolutely preventing external leakage and of closing spontaneously when the tube is left out. On the contrary, it is the most difficult of performance, is more dangerous because of the necessity of opening the stomach before the peritoneum can be sutured, requires the patient to wear a tube and remain near to the physician so that readjustments or reintroductions can promptly be made, and prohibits at any time retrograde or combined instrumentation of the œsophagus. In abstract it is thus performed: Oblique incision parallel to the left costal border, longitudinal incision of the sheath of the left rectus muscle; blunt separation of the fibres of the rectus and transversalis muscles parallel to their course, oblique incision of peritoneum. The stomach is drawn well out upon the abdomen and incised near the fundus just sufficiently to admit the passage of a quarter-inch-diameter rubber tube. The tube is then infolded by Lembert sutures, including the muscular and serous walls for a distance of one and a half inches upward in the oblique direction of the external wound and for at least half an inch below the entrance of the tube into the viscus. Next the stomach is dropped back and sutured to the parietal peritoneum all around the abdominal incision, thus closing off the operative field from the peritoneal cavity; and, finally, the abdominal incision, down to, but not including peritoneum, is closed, leaving only a snug-fitting opening in the upper portion

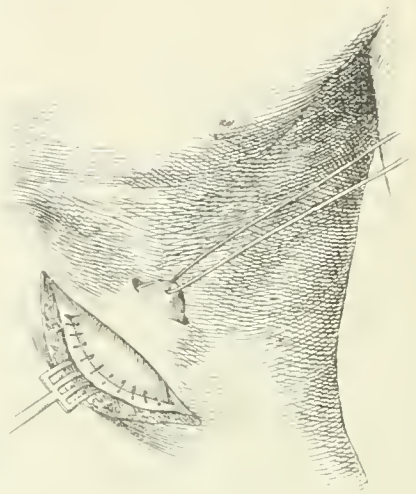
Fig. 1.



Cone of stomach drawn through incision and its base sutured to peritoneum. (Meyer.)

for the exit of the tube. Feeding, of course, may be done immediately. The long, oblique, valve-like opening effectually prevents leakage of stomach-contents, even in the absence of the tube. Great difficulty may be experienced in reintroduction of the tube should it, for any reason, be left out for a longer period than a few hours or even minutes. The fistule has remained perfect for many months in some cases, and in at least one instance has closed spontaneously when the tube was no longer worn.

Fig. 2.



Cone of stomach drawn under bridge of skin and through upper wound. (Meyer.)

In the Ssabanejew-Frank operation a three-inch, or longer, straight incision is made one finger's breadth beneath the left costal border. The underlying muscles are bluntly separated in the direction of their fibres, and the peritoneum opened in the same direction and to the full ex-

tent of the external wound. The stomach is drawn out and a long silk or silkworm-gut sling is passed through the outer coats at a point near the cardiac extremity. A cone of stomach is then drawn out to an extent of from one and a half to two inches through the wound. Steady traction

for a short time upon the sling or slings may be required to accomplish this. Then the peritoneal edges of the wound are neatly united to the serous coat of the stomach in all directions, thus at once shutting off the abdominal cavity. The muscles may likewise be sutured to the stomach if time permits. A second incision, one-half inch long, is

FIG. 4.

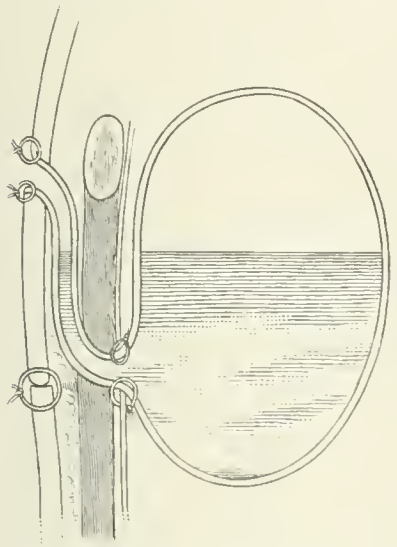

Diagram representing valve formed in Ssabanejew-Frank operation. (MEYER.)

now made about an inch above the costal border, parallel to and about the centre of the first. This is carried through skin only. The bridge of skin separating the two wounds is next separated from the cartilages by blunt dissection and the sling-thread passed beneath. Traction upon this brings the apex of the cone of stomach out of the upper wound; the original abdominal incision is then closed. Finally, the projecting portion of stomach is incised to the extent of half an inch and its mucous membrane sutured to the skin-margins of the smaller wound. Feeding may be immediate. The valve formed by the indirect opening into the stomach, and compression of the fistulous canal between the bridge of skin and the costal cartilages, has, in all cases reported, proved to be almost, if not quite, as perfect as that of Witzel. In addition, no tube need be worn, the patient can feed and care for himself, and, probably, retrograde or combined instrumentation of the œsophagus can readily be executed through it. I say probably, because it has but twice (Winslow's cases), to my knowledge, been attempted or accomplished, although I could easily pass my finger into the stomach of the case to be described without apparent disadvantage.

Ssabanejew and Frank have each performed this operation four times and secured a perfect-working fistula in every case. Meyer, of New York, to whom is due almost the entire credit of having introduced and popularized the modern gastrostomy operations in America, and to whose writings I am indebted for many of the facts, as well as the illustrations here presented, has reported three additional cases in an admirable article,[1] in which he reviews the history and minutiæ of all the proposed methods. One of his cases died on the following day; there was no leakage. The second lived seven weeks with a perfect, non-leaking fistula. A third, owing to complications incident to a preceding von Hacker operation, was not satisfactory.

Randolph Winslow[2] has reported two successful operations by this method, and was much pleased with the workings of the resultant fistules. Both were undertaken for cicatricial stenosis. One was a colored boy three years old. The artificial opening worked admirably for a year, when the little fellow died from the effects of an œsophagotomy. It was found to be perfectly feasible to practise retrograde instrumentation of the œsophagus through the dilated fistule in this case. Winslow's second case was also in a colored child, aged one year and nine months. Some suppuration followed as a result of food getting into the wound when he was fed through the fistule at the time of operation. The contents of the stomach were not so well retained in this case as in the first, yet the artificial opening acted very satisfactorily. Four months later a small bougie was passed into the stomach, and later a string was passed from the mouth through the fistule and used as a saw with which to divide the stricture. A perfect restoration of the calibre of the œsophagus resulted from subsequent dilatation with bougies, and, as the fistule was no longer required, its edges were freshened and sutured. Satisfactory closure at once resulted.

Dr. Max J. Stern, of Philadelphia,[3] operated by this method in the spring of 1894 with excellent functional result for a few days, when bronchitis produced a fatal result.

My own case, October, 1894, next follows in order of precedence; and, finally, Finney,[4] in December, 1894, performed this operation in a case of carcinoma of the œsophagus in a man aged fifty years. The stomach was not opened until "a day or two later." Ten days later, when the report was made, the fistula was working most sat-

[1] Recent Methods of Gastrostomy for Stricture of the Œsophagus, by Willy Meyer, M.D. Am. Jour. Med. Sci., October, 1894, p. 400.

[3] Personal communication.

[4] Bull. Johns Hopkins Hospital, February, 1895, p. 32.

isfactorily and not the slightest leakage had taken place.

In a subsequent communication[1] Finney states that his patient lived six and a half months and died of inanition. The action of the fistule was perfect, and leakage never occurred.

H. R., a Russian, aged fifty-one years, came to me at the Polyclinic Hospital at the suggestion of Dr. Frank W. Talley on October 4, 1894. His medical history was that of excellent health until five months previously. He had never swallowed any corrosives or sustained any injury of the throat or œsophagus. The first sign of difficulty was a little obstruction to the passage of large masses down the gullet while eating. Following this, smaller and smaller boluses were impeded or actually regurgitated. Coffee-ground material was next passed in the stools from time to time. Blood was never regurgitated or vomited. He had little or no pain; only complaining of weakness and difficulty in deglutition. Nothing but liquids could be swallowed. He had lost much flesh and was quite anæmic. Examination negative excepting œsophagus, where an obstruction was located 12 inches from the teeth and diagnosed to be probably carcinomatous. It was ascertained that the largest bougie that could be passed without force measured ⅜ inch. The constriction appeared to be about an inch in vertical extent. No bleeding followed the instrumentation.

Operation was at once proposed, as it is my belief that in all cases it is best to make a fistule so soon as emaciation begins to make itself manifest, or, as Meyer puts it, as soon as the scales show progressive loss of weight, and while the patient still has sufficient strength to bear the operation well and to ward off the bronchitis or pneumonia which kills so many gastrostomy-subjects when the operation is undertaken as a last resort.

He was liberally fed upon fluids that would pass the stricture, and while in the hospital gained considerable weight and color; but, as operation was refused, he was discharged two weeks after admission. During this time, with the kind assistance of Dr. S. Solis-Cohen, an attempt was made to pass the gastro-diaphane, but without success, owing to the tightness of the stricture. No blood was vomited or passed while he was under observation.

On October 25th he re-entered the hospital willing to submit to anything necessary to afford relief from torturing hunger, for meanwhile obstruction had become almost complete and only small quantities of fluids could be swallowed, and this with the greatest difficulty.

On October 29th, with the valued assistance of Dr. Max J. Stern, operation after the method of Ssabanejew-Frank was performed. An incision, 3½ inches long, paralled to and ¾ inch below the left costal arch, was made to the outer side of the left rectus muscle. The peritoneum was exposed and opened to the same extent. Edge of liver presented, but was pushed upward to the right, where it gave no further trouble. The stomach then came into view. It was identified by its general appearance, the direction and size of its vessels springing from the greater curvature, the origin of the omentum, and, finally, by passing a silkworm-gut suture through the serous and muscular coats, and, while traction was thereby made upon the organ, passing a finger along the upper surface until the entrance of the œsophagus into the viscus as well as the œsophageal opening of the diaphragm was accurately made out. The tumor could not be reached by the examining-finger. The organ was then strongly drawn upon by means of the suture in its wall. Thus a cone of stomach-wall 3 inches high was pulled out of the wound. Now it was seen that a suture placed 1½ inches nearer the œsophagus would approximate the base of the cone that much nearer the cardiac orifice. So another strong stitch was passed at the point indicated and the first one withdrawn. While this 3-inch cone of stomach was held out (the suture occupying the apex), a continuous suture of silk was run in three sections around its base as it emerged from the peritoneal wound. This suture united the serous and muscular layers of the stomach to the parietal peritoneum. At one or two points where approximation did not appear to be perfect an extra interrupted stitch was afterward taken. Next, an incision parallel to the first was made ¾ inch above the costal border and 1½ inches above the first or abdominal incision. This cut was ¾ inch long and was carried down through the skin only. By blunt dissection the second incision was made to communicate with the first by undermining the bridge of integument between. Now the stomach tension-suture was grasped by a forceps thrust through beneath the bridge of skin, and brought out through the upper incision. Traction upon it easily caused about one inch of the cone of stomach to protrude from the upper wound. While this was held in position the original abdominal wound was closed by interrupted silkworm-gut stitches carried down to, but not through, the peritoneum. This done, acetanilid was rubbed into the line of sutures and that opening effectually sealed off by a dressing of collodion and gauze. Then the projecting cone of stomach was opened to the extent of ⅝ inch through all of its coats in a direction corresponding to that of the cutaneous wound. The serous edges of the gastric incision were then turned over and sutured to the margins of the skin-wound. Bleeding was active from the incised stomach-wall, but soon ceased spontaneously. No outflow of gastric contents took place during or after the operation, although the patient was violently ill from the ether-anæsthesia, and the stomach-contractions were of visibly great violence owing to the œsophageal obstruction preventing vomiting. It was thought best not to feed the patient through the fistule until nausea had passed off. Washing out the viscus would have been exceedingly easy to perform, but was considered unnecessary. After acetanilid had been rubbed into the junctions of the skin and mucous membrane, a bit of protective was placed

[1] Bull. Johns Hopkins Hospital, September-October, 1895, p. 145.

over the exposed surfaces and a sterile gauze dressing applied over all and held in place by a many-tailed binder.

Rectal enemata were employed for twenty-four hours, when feeding by the fistule was commenced. Some bronchial irritation and severe cough followed the operation, but did not prove serious; no leakage took place, and no suture tore out. Primary union of the abdominal wound was secured and convalescence was uneventful. Pains were taken that the man should sit up in bed almost at once after the operation and to get out of bed within a week, so as to ward off the strong inclination to pneumonia to which these cases are so subject.

In two weeks the patient returned to his home and subsequently cared for himself perfectly with the aid of his wife. Neither of them was possessed of much intelligence, yet no trouble with the fistula occurred during the five months that he lived subsequent to the operation. The apparatus for feeding consisted of a rubber tube ⅜ inch in outside diameter and ¼ inch calibre, attached to a half-pint funnel. Through this he could feed himself with fluids with the greatest ease and expedition. Sometimes he would chew up solid food, dissolve it in fluid, and then inject the mixture as usual by gravity. By this expedient he got the digestive effects of saliva and some of the pleasure of eating. Hunger, however, was usually well satisfied by feeding through the tube. A few days after the operation, owing probably to lack of irritation incident to attempts at swallowing food, the stricture dilated and permitted of rather free deglutition; but this ease in swallowing proved of short duration, for in a week the œsophagus finally closed to the passage even of fluids. He gained constantly in weight and strength during the five months that he lived, and even had returned to his occupation as tailor, when he was taken unexpectedly with a hemorrhage (upward) from the œsophagus which almost at once killed him. Owing to the religious principles of his family no post-mortem examination could be secured.

On December 14, 1894, he was presented to the Surgical Section of the College of Physicians and the perfect working of the fistule demonstrated, as well as the ready method of feeding. During the period which elapsed between his leaving the hospital and his death I took many opportunities to see him and always found the gastric opening tight, with no surrounding excoriation.

HYPO-LEUCOCYTOSIS IN ACUTE TUBERCULOSIS.

BY ALDRED SCOTT WARTHIN, M.D., PH.D.,
OF ANN ARBOR;
INSTRUCTOR IN PATHOLOGY IN THE UNIVERSITY OF MICHIGAN.

THE differential diagnosis between general miliary tuberculosis and typhoid fever is very difficult, and so closely do cases of the tubercular affection simulate the latter disease that it is no uncommon hospital experience to see them mistaken for cases of fever and treated as such. In the majority of these cases the true state of affairs is revealed only at the post-mortem table. Points of differential diagnosis have therefore been carefully sought for, and it has been hoped that the examination of the blood in suspected cases might throw some light upon the question.

It has been demonstrated beyond doubt that in typhoid fever there is a constant diminution of the leucocytes; and the statement has been made by some writers that in acute tuberculosis the opposite condition of leucocytosis occurs, so that this has been made a differential point. Osler, in his *Text-book of Medicine*, in the paragraph on the diagnosis of general miliary tuberculosis, makes the statement that "leucocytosis occurs in acute tuberculosis, but not in typhoid fever." Laehr (*Berliner klin. Wochenschr.*, September, 1893) concludes that the practical importance of observations as to the existence of leucocytosis is evident, especially for the differential diagnosis between typhoid fever and pneumonia, meningitis, and perhaps also miliary tuberculosis. Many other writers state that leucocytosis occurs in all acute febrile diseases except typhoid, malaria, and sepsis, and only in these is there a constant diminution. But few of these observers have made any blood-counts in cases of miliary tuberculosis, and it is impossible to discover upon what ground they include this disease in the list of leucocytotic conditions. Rieder does not mention acute tuberculosis; neither does Limbeck. Neudorfer states that leucocytosis occurs in this disease only when accompanied by pneumonia, empyæma, suppurating cavities, or chronic anæmia.

On the other hand, Ewing (*New York Med. Journ.*, December, 1893) found that in acute tuberculosis resembling pneumonia there was no leucocytosis; and he emphasizes this as an important point in the diagnosis between these conditions. Cabot (*Boston Med. and Surg. Journ.*, March, 1894) makes a definite statement in regard to the matter, and says that in establishing the diagnosis between typhoid and tuberculosis the blood does not give us any aid. He was able to find in the literature only four cases of acute tuberculosis in which blood-counts had been made, and in none of these was there any leucocytosis. In one case of his own no increase of the white cells was found. Carter (*Univ. Med. Mag.*, October, 1894) says that infections show leucocytosis, with the exception of measles, typhoid fever, and tuberculosis. Zappert (*Zeitsch. f. klin. Med.*, 1893) records one case in which there was no leucocytosis and an absence of the eosinophiles.

During the past year two cases of acute miliary tuberculosis have come under my observation, and in both of these blood-counts were made for aid in establishing the diagnosis. In neither was there any leucocytosis; but, on the contrary, a constant and marked hypo-leucocytosis was found. Unfortunately, the exact records of the counts in the first

case have been lost, and in my notes I have only general statements in regard to the decrease of the leucocytes; but in the second case, which was studied from the beginning to the end of the disease, systematic counts were made, and the changes in the blood fully studied and noted. The blood-counts were made with the Thoma-Zeiss blood-counter in the usual way, using both the leucocyte-pipette and the one for the red corpuscles. The dilutions were made both with the Toison's solution and with dilute acetic acid. All possible care was taken to make the count as accurate as it could be made; and when any unusual results were obtained they were verified by several counts:

Case I.—Mr. R. K., a student, aged nineteen years, was admitted to the University Hospital on May 5th as a case of typhoid. He had been ill for five days; before that time he had been entirely well. His illness began with with nose-bleed, headache, chill, fever, and vomiting. The fever continued, and the general aspect of the case so closely resembled typhoid that the patient was sent to the hospital with that diagnosis. On admission he had a temperature of 104.5°; there was a marked typhoid condition; the abdomen was distended and tympanitic, and there was tenderness in the right iliac region. There was no eruption. The spleen was enlarged, extending three finger-breadths below the edge of the ribs. The patient had an almost constant cough, with little sputum. Numerous moist râles were heard all over both lungs, but the percussion-tone was everywhere clear. No diazo-reaction could be obtained from the urine. An examination of the blood showed a decrease in the number of the leucocytes. A provisional diagnosis of typhoid fever was made, and the baths were begun at once.

The patient remained in the hospital three weeks. During the first week it became evident that the case was not one of typhoid. Pulmonary signs and symptoms rapidly developed, so that four days after admission there was tympanitic resonance over the lungs, with blowing breathing and increased râles. The expectoration became profuse, and numerous examinations for tubercle-bacilli were made, but these were negative. During this first week many examinations of the blood were made, and at all times a hypo-leucocytosis was found. This was very striking in the stained covers; in ordinarily thick covers but few could be found. It was noted that none of these contained eosinophiles. Many covers of blood were also stained for tubercle-bacilli, with negative results.

Two weeks after admission and nineteen days after the first symptoms of illness elastic tissue and tubercle-bacilli were found in the sputum, and the suspected diagnosis of acute tuberculosis was confirmed. Death occurred after patient's removal home, seven weeks from the beginning of the disease.

Case II.—Mr. H. G., a farmer, was admitted for tuberculosis of the genito-urinary tract. His right testis was removed on December 3, 1894. He bore the operation well, and on the next day his general condition seemed improved; but two days after, his temperature, which had decreased after the operation, rose to 104°, and the patient passed rapidly into a marked typhoid condition of stupor and delirium. The spleen was greatly enlarged, and the diazo-reaction was many times obtained in the urine. Pulmonary signs soon appeared; there was marked tympanitic resonance, with râles and blowing breathing all over the lungs. No tubercle-bacilli were found in the sputum or in the blood, though diligent search was made for them. From the nature of the case there could be no doubt as to the diagnosis of general miliary tuberculosis. Death took place on January 6, 1895. The autopsy showed a typical picture of exquisite general miliary tuberculosis. There were also old suppurating foci in the right lower lobe and in both seminal vesicles. The right one was greatly enlarged, nearly four ounces of pus rich in tubercle-bacilli being obtained from it. The existence of these suppurating foci must be emphasized in connection with the hypo-leucocytosis, which was, as I shall show, constantly present.

Systematic blood-counts were made in this case during its entire progress, and I give the records of some of these in order to show the marked diminution of the leucocytes. These counts were made at least four times daily, on some days during every hour between eight in the morning and six in the afternoon. The count of the leucocytes varied greatly from hour to hour, as may be seen from the record; but from the great care used, and the verification of the results by repeated observations, these variations cannot be considered as the results of faulty technique:

Patient died at 12.50.	

These observations, chosen at varying intervals from the record, may serve to show the hypo-leucocytosis that was constantly present during the whole course of the disease. There was no decided relation between the temperature-curve and the number of leucocytes, though as a rule the highest counts were coincident with the highest temperatures. The very low count, 600, on the third of January, was confirmed by several examinations. At the time of the observation the patient was in a severe chill; his temperature was 104.5°; the surface of the body and the extremities were cold. The blood was very dark, and did not flow freely. A diminution of the leucocytes in the peripheral circulation during a chill has been noticed by other observers. The ante-mortem increase is also well known, having been many times observed.

The microscopical examination of the fresh blood showed many large swollen leucocytes, highly refractive; in several cases the nuclei could be seen slipping out of the cell. Many covers were stained, and differential counts made from these. These counts showed at all times an increase in the polynuclears and a diminution in the lymphocytes; no eosinophiles were ever found. The proportion stood usually thus:

Polynuclear and transitional forms	91.49 per cent.
Lymphocytes	5.22 " "
Large mononuclears	3.09 " "
Myelocytes	.20 " "
Eosinophiles	——

The observations made in these two cases confirm Cabot's statement that the blood does not give us any aid in the diagnosis between typhoid and acute tuberculosis. Whether the hypo-leucocytosis is a marked feature of the latter disease, as it is of typhoid, must be shown by further observations; but the fact that a decided diminution of the leucocytes is present should not in any doubtful diagnosis turn the scale in favor of typhoid fever; for these two cases certainly prove that there may be in acute tuberculosis, even when suppurating foci are present, a hypo-leucocytosis even more marked than that usually seen in typhoid. Therefore, though we are as helpless as before, so far as the differential diagnosis is concerned, these observations may serve in extending our knowledge of the tubercular affection, and save us from drawing conclusions based upon a misconception of its nature.

Further, this great decrease in the sum total of the leucocytes, with relative increase of the polynuclears occurring in a severe and general infection, leads to many interesting speculations. Is there an absolute decrease of the white cells, or is the decrease limited only to the peripheral circulation? Are the cells destroyed, or is the leucocyte-forming power of the body diminished? Do the swollen leucocytes from which the nuclei can be seen escaping mean that the cell is being broken up—that nuclein, or some other antitoxin or germicide, is being set free—that the process is part of the body's antagonism to infection? These questions, so important to us, because of their relation to the treatment of disease, can be answered only by more extended and detailed study of leucocytotic conditions.

LABORATORY OF CLINICAL MEDICINE,
UNIVERSITY OF MICHIGAN.

NOTE.—Since the above was written, the second edition of Osler's text-book has appeared. In the chapter on "Acute Tuberculosis" the statement quoted above has been modified to the following: "The blood may show a slight leucocytosis, but in the very acute cases where there are no suppurating foci this is absent."

DOUBLE CASTRATION FOR HYPERTROPHY OF THE PROSTATE, WITH REPORT OF A CASE.[1]

BY CARL MEYER, M.D.,
LECTURER ON PATHOLOGY IN THE GROSS MEDICAL COLLEGE, DENVER, COL.

CASTRATION is an operation as old as mankind; castration for the special purpose of reducing the hypertrophic prostate gland is a surgical success of the last two and one-half years.

Its surgery is a science of facts, and not of theoretical suggestions. The unquestionable honor of having performed the first double castration with the clear and distinct aim mentioned above belongs to the Norwegian surgeon, Ramm. To the Philadelphia surgeon, White, on the other hand, belongs the honor to have been the first to suggest the operation theoretically; but while White was still busy with his experiments on dogs, Ramm had already performed the operation on man.

Haynes, Fremont Smith, White, Finney followed and reported successful cases, and by and by the operation was performed by many surgeons all over.

Wassidlo, early in 1895,[2] published a series of forty-three successful operations, the ages of the patients ranging from sixty to eighty-one years. Before the operation there was great difficulty in emptying the bladder and more or less cystitis. In all of the forty-three cases castration was performed on both sides, and an improvement in the cystitis and micturition always resulted a short time after the operation. In all cases there was shrinking of the enlarged gland.

White, in his last paper, "The Results of Double Castration in Hypertrophy of the Prostate,"[3] re-

DR. CARL MEYER, *Fecit*.

ports 111 cases, with a mortality of 18 per cent. (20 deaths); but on 13 of these 20 the operation was performed *in extremis*, or as a last chance, and the remaining 7 died of morbid changes of the kidneys and bladder which would have proved fatal without operation.[1]

The fact that hypertrophy of the prostate gland is in very many cases the direct cause of retention of urine and cystitis, ailments which are among the most troublesome and dangerous diseases of elderly people, has resulted in the proposition of many different operations, but their value cannot be compared with double castration.

The *cystotomia* with drainage and a permanent fistula is not a radical operation because the hypertrophied prostate is not reduced.

The *perineal prostatotomia*, or rather enucleation of the prostate, has only a mortality of about 5 per cent., but is often followed by a painful fistula.

The *suprapubic prostatectomia* is a dangerous operation and also followed by a fistula.

The destroying of a small part of the hypertrophic prostate by the *galvano-caustic methods* from the urethra will reduce only a little of the gland.

Ligation of the whole spermatic cord or of the spermatic artery is sometimes followed by gangrene, and its effect on the prostate is also doubtful.

The *subcutaneous section* of the vas deferens seems to have some reducing influence on the hypertrophic prostate, but it does not act so promptly as double castration, and, besides, it destroys also the physiological functions of the testicle.

Under certain conditions and in cases where we want a prompt and radical result of our activity, in cases, too, where the physiological functions of the testicles do not play any *rôle*, the double castration may be considered as the ideal treatment for hypertrophy of the prostate.

But the operation itself should be limited to severe cases of cystitis with more or less complete retention of urine, to cases not too far gone nor complicated with important morbid changes of the kidneys, as pyelonephritis or uræmic poisoning, otherwise the result will be a bad one, and the operation discredited.

To perform double castration on an emaciated individual in the stage of uræmic poisoning, or in a case complicated with pyelonephritis or other severe morbid changes of the kidneys, is as foolish as to perform tracheotomy in a case of membranous croup of the lower bronchial tubes, or in a case of general diphtheria.

If we are careful in selecting our cases which answer the above-mentioned indications, cases which will not succumb to other morbid changes of the organism a few days after operation, double castration will not have a mortality of 18 per cent., but will be a life-saving operation; but if we perform double castration just because an individual has retention of urine, cystitis, and a hypertrophied prostate, and if we neglect to study carefully the conditions of the other organs, in many cases the patient will die, and the operation will become discredited.

The question arises: Can we explain the effect of castration on the hypertrophied prostate?

White, in the above-mentioned paper, summarizes his opinion as follows:

"The function of the testis, like that of the ovary, is twofold: 1, the reproduction of the species, and, 2, the development and preservation of the sexual characteristics of the individual.

"The need for the exercise of the latter function ceases when full adult life is reached, but it is possible that the activity of the testis and ovary in this respect does not disappear coincidently, and that hypertrophies in closely allied organs like the prostate and uterus are the result of this misdirected energy, etc."

With this opinion White stands not alone. But analogies are not explanation, nor can experiments on young, powerful dogs, full of vitality, be compared with operations upon old men with chronic cystitis, retention of urine, and other morbid changes; and last, but not least, the physiological and anatomical relations between ovary and uterus are of a much more delicate and closely related character than those between testicle and prostate. I cannot believe in a misdirected energy where we have to deal with cystic and fatty degenerated organs in the stage of chronic inflammation (*vide* later).

Other authors claim that the effect is entirely due to some unknown influence from the central nervous system. Again, I cannot believe that the removal of a fatty and cystic degenerated organ which has ceased to fulfil any physiological functions, the removal of which, too, has no influence at all on the body or mind of the individual, can have such an effect on the central nervous system as to produce an *immediate* shrinking of another organ.

I think it must be possible to find the real cause of the fact in some anatomical or, better, pathological change of the respective tissues; and after a careful investigation in my case I believe this cause can be found in "pathological alterations of the circulatory system to some extent already existing before the operation." It is a fact that after every operation on the testicles the scrotum undergoes atrophy; it shrinks to a small lump of connective

[1] White's table shows: 14 deaths from uræmia, 2 from pneumonia, 1 from nephritis, 1 from exhaustion, 1 from heart-failure, 1 from hemiplegia; total, 20.

tissue, fatty tissue, and skin. Not only the scrotum, but the penis too becomes smaller, and also the prostate gland. Very often after castration the patients complain of a cold feeling in the penis, as did my patient.

Now, atrophy is mostly a consequence of incomplete and imperfect nutrition and circulation, either from want of oxygen or from some morbid changes of the bloodvessels.

Through castration a large number of bloodvessels, besides the spermatic artery and nerves of the dartos, are altered in such a way that many of them become obliterated, and thrombosis takes place; and this thrombosis, especially of the veins, may extend to some of the veins of the prostate gland, as there are numerous anastomoses between the venous plexus pudendalis and vesicalis. When the bloodvessels are obliterated not only the smaller veins, but the capillaries and arterioles, as well as the respective tissues, are deprived of the necessary supply of blood and atrophy—fatty degeneration—is the result.

Such obliteration of the bloodvessels may also result from *a direct nervous influence*. We know that the plexus prostaticus of the sympathetic nerve is in close connection with the plexus vesicalis, which also gives branches to the vas deferens. These plexuses contain vasomotor fibres, irritation of which is followed by "narrowing" of the respective vessels. Without doubt the bloodvessels in cases of chronic cystitis and hypertrophied prostate are already in such a morbid condition (mostly fatty degeneration and chronic inflammation of the vessel-walls) as to be "immensely predisposed to the formation of thromboid obliteration."

And from such pathological facts, I believe that the "real cause of the shrinking of the prostate gland after double castration is *impaired nutrition*," as a consequence of obliteration of the bloodvessels caused by a combination of the reasons above mentioned.

Report of a case:

Mr. J., from Denver, aged seventy years, called at my office complaining of a complete retention of the urine for the last two or three days. Patient is a robust man, and claims never to have been sick except for various ailments of the bladder. As a schoolboy patient had been troubled with a urinary disease of an unknown character. He remembers very well that his abdomen became swollen and that during the school-hours he frequently had to go out to urinate. As a soldier he was sometimes unable to serve as a sentinel, because he could not hold his urine for two hours of duty. In this time he had several gonorrhœas and strictures, but no syphilis. Afterward he lived as an innkeeper and farmer; free drinker of beer and wine; is married and the father of healthy children. In the last few years his condition has become worse; urination is more frequent and causes him to rise six or eight times each night. The passage of an ounce or two of urine was always the result of active abdominal compression and frequently attended by defecation.

In the latter part of September the patient, while fishing, stood for several hours up to the hips in cold water, resulting in complete retention of urine.

Examination. Bladder forming a round, pear-shaped tumor, easily recognizable on inspection of the abdomen; top of the bladder reaches the navel; whole region sensitive to touch. The rectal examination shows an immensely enlarged, hard prostate gland the size of a man's fist. Left lobe especially enlarged. The covering mucous membrane is very tight and closely adherent to the gland.

After injection of ½ per cent. cocaine in the urethra (which always may be used before catheterization in difficult cases), I relieved the patient of 5½ pints of urine, of a dark yellowish-color; specific gravity 1024; alkaline reaction; abundant, whitish sediment; traces of albumin. The catheter, before entering the bladder, slipped through a narrow, hard mass, at least one and a half inches in length, at which place patient had a peculiar gnashing and crashing feeling.

The microscopical examination of the urine showed the presence of chronic purulent cystitis, but no symptoms of nephritis.

Therapy. As the retention proved to be complete, and as it was impossible to apply a soft, permanent catheter, the bladder was emptied and washed out every twelve hours. As a few days later it became impossible to introduce either a normal, a prostatic, or a flexible catheter, I got, by the courtesy of Dr. See, a catheter of an old type, which was recommended for such desperate cases long ago by Dr. Andrews, of Chicago. The application of this catheter was astonishingly easy.

As the patient was unable to apply the catheter himself, as the cystitis did not greatly improve, and as about a week after beginning treatment patient had two chills, with a rise of temperature to 100° and some somnolence, I insisted on double castration, which was performed on October 12th in the usual way.

The removed testicles were both degenerated on the surface, small cysts covering the tunica vaginalis propria; these cysts were filled partly with a mucoid and partly with a colloid substance. On the right testicle we found a hydrocele, tunica propria thickened; also tunica albuginea; glandular part of the testis atrophied, of a fatty, white, gross appearance; walls of the vas deferens of the spermatic artery thickened; lumen of the arteries gaping.

Microscopical examination after hardening in alcohol and staining with hæmatoxylin: Interstitial tissue of the gland not hypertrophied; seminiferous tubes partly fatty degenerated, partly filled with immigrated round cells, of a homogeneous or gran-

ular type, some with distinct nuclei; epithelium of the seminiferous tubes not recognizable; no spermatozoa; some seminiferous tubes are obstructed with a homogeneous light mass (hyaline). Chronic parenchymatous inflammation, fatty and hyaline degeneration.

Vas deferens: columnar epithelium absent; lumen of the vas very small; layer of connective tissue much thickened, partly with formation of new connective tissue. The vessels (especially the arteries) of the spermatic cord show no endothelial lining; the whole wall is a very thick layer of connective tissue, with newly formed connective-tissue cells, partly with some immigrated round cells; in a few places we see fatty degeneration in the vessel-wall near the lumen; chronic inflammation of the vessels. (*Vide* drawings.)

The patient recovered nicely from the operation, the wound healing by primary union. The bladder was irrigated twice daily until the twelfth day. On the sixth day there was a voluntary discharge of a half-drachm of urine, and on the following day of several ounces. Further use of the catheter was unnecessary after the twelfth day, when shrinking in the prostate gland was easily recognized. After five weeks this body was one-half to two-thirds its former size, much flattened in shape, and the mucous membrane overlying it freely movable.

Patient declares that never in the last fifty years could he hold his urine as long as he can now (five to six hours). Micturition is of a normal character, with a strong stream. Bladder-wall contracts after emptying.

Urine: Clear, light, acid; specific gravity 1016. Very little sediment, consisting of a few round cells.

This I call an ideal case in every particular, showing clearly and distinctly progressive ailment of about fifty years' duration, which presented an absolute indication for some surgical procedure, not only for the relief from the local disease, but from the threatening uræmic poisoning, which certainly in a few days more would have rendered any operation useless.

No matter what difference of opinion may be entertained by surgeons upon this point, such cases as this indicate forcibly that double castration should be regarded as a standard treatment for hypertrophy of the prostate gland.

As the operation itself, done properly and in time, involves no danger, but in every case is life-saving, it should be performed without hesitation, at least in all cases where the physiological functions of the testicles are nearly or entirely gone.

NEW YORK is being congratulated from every direction on her good fortune in securing the services of Dr. John S. Billings as Chief Librarian of the Consolidated Libraries of the City. Dr. Billings will here find a congenial field for the exercise of his superior powers of organization.

THE PATHOLOGY OF SOME UNUSUAL CONDITIONS IN ACUTE STRANGULATED HERNIA.[1]

BY F. CAUTHORN, A.M., M.D.,
OF PORTLAND, OREGON;
VISITING SURGEON TO ST. VINCENT'S HOSPITAL; SURGEON N. P. R. R.; LATE PROFESSOR OF SURGERY, MEDICAL DEPARTMENT OF WILLAMETTE UNIVERSITY, ETC.

IT is not my intention, in presenting this paper for your consideration, to enter into a discussion of the subject of hernia in general, however important the subject may be from a surgical standpoint; but rather to call attention to some special conditions that I have met with in practice that are not fully considered in any work on surgery with which I am familiar. As the result of this experience, I have been led to draw certain conclusions as to the pathology, diagnosis, and management of these conditions, which I have for some time wished to bring to your attention, that we may thus compare notes to our mutual advantage.

I am sure that there would be but little difference of opinion between us as to the management of a case of strangulated hernia presenting all the cardinal symptoms, as represented by an increase in size of the hernial tumor, pain, irreducibility, and absence of impulse, associated with evidence of shock and vomiting, going through its various degrees up to the stercoraceous. We are seldom at a loss as to what to do in typical cases of any disease. It is the atypical case, the one that in many essential particulars conforms to the rule, but in many others does not, that puzzles the judgment and causes too often a fatal delay in instituting the proper procedures for its relief. It has been my peculiar fortune to meet with several such cases of strangulated hernia; in fact, with such a number that I am inclined to believe these conditions prevail to a larger degree than is commonly thought. In the first place, there are various degrees of strangulation—an essential point to be borne in mind. In its simplest degree it is merely a constriction sufficient to occlude the caliber of the intestine, without marked disturbance of the blood-supply. In its most exaggerated form it is the complete arrest of the circulation in addition. Perhaps in those cases of acute hernia brought on by violent efforts in a person not before subject to a hernia the second condition prevails almost from the beginning. Of cases of acute strangulation of previously existing hernia, I believe the great majority go through all these degrees, if left to themselves.

Before proceeding further I desire to say something of the pathology of strangulation in general.

I think we may set it down as a fact that it is never due to an actual contraction primarily of the neck of the sac or the surrounding tissues—a theory

[1] Read before the Oregon State Medical Society, June, 1895.

that was so long held. There is a *relative* narrowing of the neck of the sac by reason of an *absolute* increase of the contained parts. Let us consider for a moment how this comes about. A man suffering from a reducible rupture undergoes some severe exertion, and finds that the hernia is no longer reducible. A larger amount of the intestine than usual is forced into the neck of the sac, which we may suppose has yielded of its own resiliency, however slightly, and now makes constriction at this point by just this amount of resiliency. The return of venous blood is impeded—not stopped entirely—and a passive congestion of the gut ensues, with swelling. The constriction is increased *pari passu* with this increase in size of the tumor, *relatively* but not *absolutely*, until the caliber of the gut is occluded. The congestion being within the sac, more intestine may be forced through the neck by coughing or bearing down, and thus the hernial tumor may be sometimes indefinitely increased in size; but when the taxis is employed we find we can only reduce this superadded and uncongested portion. As the congested part approaches the neck there is not room to accommodate it, and the contents of the intestines, flatus or gas, are stripped back, thus forming an insuperable obstacle to complete reduction.

This is the explanation I have to offer of those cases in which there is impulse on coughing, with possible increase in size of tumor, and in which from lack of complete obstruction to the blood-supply there is absence of the more severe symptoms of shock and vomiting, etc., in the early stages.

The condition is only remediable by operation, and is a very deceptive one, and too often causes a delay by the absence of the typical signs of strangulation. Its recognition is not a mater of so much importance to the surgeon who would operate early in any case of hernia that could not be reduced; but, unfortunately, this view is not held by many general practitioners, and thus they are deluded into temporizing with hot and cold applications with opium, and repeated trials of the taxis, until the last degree of strangulation is reached, and irretrievable damage has been done.

The general outlines of the following case will illustrate what I have tried to say in regard to these cases of partial strangulation:

I was called to see Mr. P., aged sixty-six years, who had suffered for years from a rupture. Six days previously he had, while at work, suddenly felt his rupture come down, and experienced a severe, sharp pain at the same time. His own efforts at taxis failed, and a physician was called, who arrived several hours afterward, and who also likewise failed at reduction. However, after a few hours the local pain and soreness subsided. There was occasional vomiting, bilious in character, four or five times in the twenty-four hours, until the day upon which I saw him, when it became suspiciously stercoraceous. He was comfortable, but weak. A local examination showed a moderate hernia, which gave distinct impulse on coughing, and which could be increased in size indefinitely by bearing down. Efforts at taxis were followed by easy reduction of the larger part of the mass, but at the internal ring there always remained a perceptible amount that could not be reduced. His medical attendant stated that this had been the history of the case since its beginning. An operation was performed, and the condition described was found. The gut was congested and thickened, but not to such an extent as to endanger its vitality. The patient lived about thirty-six hours, and died of exhaustion incident to inanition and the prolongation of the mild degree of shock. There had been during the whole time no really alarming symptom, except the inability to reduce the tumor completely, and the very gradual progressive exhaustion.

The moral I would have drawn from this case is this: *No matter how mild the constitutional symptoms, no matter how nearly the rupture may be reduced, if it cannot be entirely reduced, do not wait more than a few hours before resorting to operation.*

The other and more important class of cases to which I wish to call your attention is represented by the so-called "reduction en masse," or "en block," or the "properitoneal hernia" of Krönlein," and I wish to introduce what I have to say on this subject by giving an outline of two cases that I have met with:

Case I.—A steamboat-man, about thirty years of age, had suffered for years from a rupture, for which he had worn a truss. While trucking upon the boat his hernia came down, and was reduced by a physician and the truss reapplied. After a day or two's rest in hospital he again went to work, but complained that things did not feel right at the site of the hernia. An examination failed to show the presence of the hernia. The rings were very much enlarged, and lay directly over one another, as in old herniæ, thus leaving a direct opening into the abdomen. The finger could be passed into the abdominal cavity to its full length, and twisted around without difficulty. He presented some symptoms of strangulation, however, in the way of vomiting, etc., and was sent to the hospital, and came under the care of Dr. G. B. Young, formerly U. S. M. Surgeon at this station. By the following day his general symptoms were all worse, and Dr. Young asked me to see him again. The local condition was the same as the day before. *Percussion* over the ring gave distinct dulness, which at the time was difficult to account for, but it suggested that something was wrong at this point, and this, together with his general symptoms, caused us to operate and ascertain the condition. The sac was found entirely within the abdominal cavity, the neck—the point of constriction—having been sepa-

rated from its attachments at the ring, lying fully four inches away from the abdominal wall. (*Vide* Fig. 1.) An amount of intestine represented approximately by the size of the fist was strangulated, and very much congested and thickened. The neck of the sac was pulled up and cut. The blood-supply soon re-established itself, and the intestine was returned. The patient made a good recovery.

CASE II.—A man, about fifty-years years old, had suffered for years from hernia. He had worn a truss which had kept it in place. Six days before I saw him his hernia had come down and had been reduced, but he complained of pain within the abdomen on the same side. The canal was patulous, and the finger could be pressed up to and within the internal ring, meeting at this point with an elastic tumor. General condition was extremely bad; there was profound prostration of the nervous system, stercoraceous vomiting, etc. Percussion showed dulness over the internal ring, which extended toward the median line, well behind the rectus muscle. Diagnosis was made of strangulation within the abdomen, and although well-nigh hopeless an operation was advised and done. A free incision was made with the upper limit well above the internal ring, and all the structures cut down to this point. The various components of the cord were recognized, but I confess to have been sorely puzzled at the entire absence of anything that looked like a hernial sac. The internal ring was enlarged, and just within presented this elastic cyst-like tumor. I determined to find out just what condition of things was present, and very carefully cut into this tumor, which proved to be the intensely distended hernial sac. There was an immediate escape of a large amount of bloody, foul-smelling serum, and a mass of intestine of the size of the double-fist, black and gangrenous, presented. The neck of the sac was found to lie well behind the rectus muscle, and nearly in the median line. (*Vide* Fig. 2.) It could now be lifted up and brought forward, which was done, and the constriction cut. Some ten inches of the sphacelated gut was removed, and on account of the condition of the patient the two ends were stitched to the external wound, and the operation hurriedly completed.

The progressive sepsis that was present at the time and profound prostration continued, and the patient died in about thirty-six hours.

An earlier recognition of the condition would undoubtedly have been successful as in the other case.

The only difference between the two cases consisted of the greater amount of serum in the latter case, the sac being distended by it to its full capacity.

Pathology: The two cases present the following peculiarities: In both cases the sac was entirely within the abdomen, the neck being removed from the internal ring by several inches. The question arises, How is such a condition brought about? These cases were both cases of long standing, and both had worn trusses for years. It seems to me that in this fact lies the solution of the problem. The element of time, combined with the pressure of the truss, supplies the essential conditions. Upon the first appearance of the rupture, and while the sac is small, the truss is applied. This keeps the hernial mass within the abdominal cavity. Let us suppose a certain degree of laxity of attachment of the neck of the sac to the internal ring. A small amount of intestine may then find its way into the sac, but is prevented from coming down by the presence of the truss. The pressure thus exerted presses the neck back from its attachment to the ring, and thus as it recedes the hernial sac increases in size and comes to lie entirely within the abdominal cavity. The conditions determining strangulation are, of course, the same as in any other case of rupture, except that the constricting tissues are solely the puckered folds of thickened peritoneum at the neck of the sac.

FIG. 1.

FIG. 2.

FIG. 3.

I wish to emphasize the importance of *percussion* in recognizing this condition, as it is the point of most importance, and one which I have never seen referred to in this connection. It has been resorted to to determine the contents of a hernial mass exter-

nally, but not to determine the presence of *internal strangulation.* If percussion over the internal ring gives dulness or flatness, it indicates the presence of something abnormal—in this case the presence of congested intestine with more or less serum in the sac—and if associated with other symptoms of strangulation indicates the site of the trouble. Again, it should be of value after reduction as indicating whether the reduction is complete or merely the return of the sac with its contents into the abdominal cavity.

It seems to me that these two cases strongly indicate that all cases of reduction en masse are simply the return of the intestine into a preformed sac, which, under ordinary circumstances and under the pressure of the truss, normally lies within the abdominal cavity. I cannot believe that taxis ever strips up the neck of a sac primarily as our textbooks would have us believe.

The accompanying diagrams may help to elucidate what I have attempted to explain in regard to the above conditions.

THE PREVENTION OF SOCIAL DEFECTIVES.[1]

BY R. M. PHELPS, A.M., M.D.,
OF ROCHESTER, MINN.;
ASSISTANT SUPERINTENDENT, MINNESOTA STATE HOSPITAL.

THE purpose of the present paper is to set forth forcibly how much better and easier it would be to apply prevention to the problem of our defective classes than to let things go as they please, and then try to patch up the results; to try to prevent the existence of defectives, than to cure their defectiveness. Of a given population of one million souls in almost any of our fair States, including idiots, imbeciles, epileptics, insane, deaf-mutes, and certain of reform-school children, there may be fairly estimated to be about six thousand so definitely defective that the defectiveness is clearly apparent to all about them. This is about one person in every one hundred and seventy. I have made a roughly approximate estimate, formed from the opinions of others, variously secured. Estimating in this way, we can make out a table about as follows:

Most appropriately called defectives—

1. Idiots, imbeciles, and feeble-minded	1.50 to 1000
2. Deaf-mutes	.67 to 1000
3. Insane	2.00 to 1000
4. Epileptics	1.50 to 1000
5. Perverts and defectives of reform-school type	

More loosely called defectives—

6. Blind	.97 to 1000
7. Deformed or paralyzed	
	6.64 to 10000

Sometimes included as defectives—

8. Paupers (in almshouses or quite fully supported)	1.32 to 1000
9. Tramps	.75 to 1000
10. Inebriates, extreme	1.00 to 1000
11. Criminal classes (in prisons)	1.16 to 1000
	10.87 to 1000

To this may be added, as largely dependent rather than defective—

12. The helpless aged	50.00 to 1000
13. Children under twenty years of age	450.00 to 1000
14. Physically sick at any time	40.00 to 1000
15. All others doing nothing, wholly dependent.	

The "defectives" are, of course, only a small portion of that larger class called "dependents," which must include at any one time all physically sick, all young children, as well as all the healthy people who, for one reason or other, are relaxed into complete dependence. Broadly speaking, each productive working-person has to support not only himself, but one other person in a state of dependence. So ground into our system of living is this subject of dependence that we never think of rebelling at the need of supporting the criminals, the defectives, and our dependent relatives. Immense as the question is financially, we must here drop the consideration of it with this reference.

But the mental defects and the mentally defective ones, though not all dependent by any means, are a blot on our humanity—a reflection on our mental integrity as a race and our good judgment as a generation. They not only carry the most bitter regrets possible into many a family, but they reach out in their reflections and insinuations till we all shrink lest we be tainted with a like curse.

What are the causes of all this defectiveness? and, more especially, What can we do about it? are questions, the central elements of which have been largely suppressed in public considerations, but which we think ought to be fully discussed. Idiocy, imbecility, feeble-mindedness, perversions, and epilepsies undoubtedly do *not* exist without causes, but these causes are unfortunately in their histories obscured. It is here that we begin to touch on that subject, "heredity"—a subject which so touches the bare nerves of each one of us that we feel like shrinking; and, indeed, most people do shrink and avoid its consideration, and yet, because so vital, it is most useful to study. It *does* make some difference to the child what kind of man and woman his parents are; nay, more, this makes more of difference than any other cause one may mention. Heredity is not a freakish and occasional thing, showing itself only by peculiarities of feature or of conduct, but it is a *steady and constant element* that gives a trend to the whole of

[1] Presented before the Minnesota State Conference of Corrections and Charities, at Faribault, Minn., October 30, 1895.

a man's constitution. That one should not inherit is the exceptional and strange thing. All that we start out with is inherited, not merely some striking peculiarity. Some form is inserted into the elements of our bodily structure, by which they not only start out poorly or well, but by which, moreover, they are influenced throughout life; by which, even late in life, they fall before insanity, or consumption, or other elements. Moreover, heredity must be considered not by following insanity alone, nor epilepsy alone, nor imbecility alone, but by all those and the many others which depend on nerve- and brain-structure, each of which may be handed down changed to any other.

So many defectives are there that the subject reflects upon many of us in an unpleasant way, and we will likely try to thrust it back; but to do this is but to invite their continuance. To clean up the record for future generations we must *study*, not ignore, this cause; nay, we must even face *our own peculiarities*. Logically, if inheritance is a cause of defectiveness, we should study the subject with all its relations, both personal and general. Taking, first, the grosser forms of insanity, imbecility, and early epilepsy, defectiveness in one or both parents is undoubtedly a most important cause. Sometimes this defect is evident to everyone; often it lies back as an insanity or as a yet undeveloped liability to insanity; often, moreover, it lies as some partially developed defectiveness in one parent fully developed in a child, still as a true heredity. At times some debilitating physical disease invades the nervous system of the parent, like consumption, alcoholism, or syphilis, and the offspring are neurotic, epileptic, or eccentric in some way. In the subject of insanity I am often pointed to our statistics showing only about 25 per cent. as inherited, and am asked why statistics do not more fully uphold my statements. The reasons are as above. Many parents die before insanity develops. If a man is only half insane—that is, defective in a medium or mild degree—and his son is insane, going to an asylum, the case is rarely reported as an inheritance. On the other hand, if the man is insane and the son only defective in a moderately feeble or erratic way, it is also rarely reported. If a man is syphilitic or grossly inebriate, and a son is insane, it is not counted. If a son is insane through any more temporary parental cause, it is not reported; and, again, in many cases well-known facts are suppressed or misrepresented by the parents, sometimes through ignorance, sometimes because of the stigma thereby attached. Finally the histories of our patients are comparatively unknown; rarely can we personally judge of the parents.

Right here we will be asked what defectiveness includes, any way; and we would say, as simply and untechnically as we can, that *it is the lack of the full development of one or more of the faculties, usually mental, sometimes physical, or the irregular, imperfect, or unbalanced development of them.* We in this discussion include insanity as well as imbecility. At once, too, as a flash will follow in the logical mind the question, Are we any of us *perfectly* balanced or perfectly developed in all our faculties?—a question that is fundamental, and one which the psychologist must face even if the untrained popular observer is content to slight as too technical and quibbling a point. By scriptural warning, and all popular thought, we have been so many times told that "no one is perfect" that the practical application would seem to follow, almost inevitably. That men are of "all degrees of ability" is commonly said; that children are of all "degrees of brightness" is also a common expression; but that men are of differing degrees of "debility," or at times of *insanity*, and that children are of differing degrees of *feeble-mindedness*, can rarely be found in the written language. Does not one involve the other to a certain degree, even as mountains involve the existence of valleys? "Abilities" are not commonly due so much to differences in application as to differences in native ability.

It is, however, the cases in which these disabilities become *gross* that we are considering, and those only. We do not wish to confuse the line between disability and disease unnecessarily, nor more than the facts will permit. They mingle a good deal, whether we admit it or not, and more so in mental than in physical lines. We feel little sympathy for the Nordau type of criticism, yet recognize the above fact as giving it a partial foundation.

Next we ask ourselves, Can these forms of defectiveness (meaning now the grosser defectiveness) be induced by some cause acting after birth? Mental as well as physical impairment certainly can be induced by head-injuries and severe diseases, but such defects are usually of rather different type. Moreover, ordinary causes rarely can produce feebleness of mind, except a predisposition exist; in which case the predisposition is essentially the cause, and *predisposition* is usually a true heredity, as yet undeveloped. Among such causes we may name prominently fractures of the skull, sunstroke, typhoid fever, and scarlet fever.

In general, then, we would find the most common cause of defectiveness to be an inherited constitution; which may be in the one case an eminently defective one, in the other case one easily liable to defectiveness or which tends toward it later in life. It will, perhaps, disappoint some if I do not dilate upon inebriety, dissipation, sexual vices, and our so-called fast living of modern life, as causes of

defectiveness, and, perhaps, also upon such causes as severe diseases, changes of the climate, etc. But the final point is that even these seem to need the inheritance of a susceptible organization in order to be effective. For example, of twenty-five men who drink equally under equal conditions, at a rough estimate, only about one shows mental failure. Is it not the different inherited constitution that determines this? I think you will find it so. And so you will find it throughout the list. Even the criminal classes are, by some popular literature, held to tend toward criminality by reason of direct or indirect inheritance.

The subject of prevention then seeks for causes, and the causes point us toward, first, one's inheritance; secondly, that right living which seeks to prevent the fruition of that inheritance.

Under the first section, we would say that we consider that the time is ripe for such legal measures as one which will *prevent the marriage of an epileptic, or of one who has suffered from an attack of insanity.* Perhaps this is as far as I should venture at the present time, lest the timid ones overwhelm the whole motion with their objections. I do not doubt, however, that in some future time laws will go much further than this, for it is very doubtful if persons with pronounced tuberculosis of the lungs should marry. Children of the insane are occasionally in a painfully doubtful position. Many other thoughts suggest themselves.

I do not attempt further argument for such a law than is contained in the preceding statements. If the children of an epileptic were *always* epileptic or grossly defective, doubtless I would have few objectors. Likewise, if the children of the insane were *always* insane or otherwise defective. But we think that the claim that a certain proportion, say 25 or 50 per cent., will show defectiveness is argument enough. Especially as to the alienist minor defective strains are noticed in others of the family. I have purposely made the above statements rather bluntly. You are left to consider, first, if such statements are true; secondly, if being true, should not such laws as are above mentioned be enacted?

The first part of our prevention, then, is that we have laws to prevent the transmission of the more gross defectiveness. The second part of the preventive measures leads us toward an *education* of people which shall induce them voluntarily to avoid marriage or offspring because of consumption, insanity, inebriety, etc. However, if persons are grossly defective mentally, such education will not be of value to them, their minds being too defective to be so controlled. In many cases, however, it will do good.

The main educating element, however, is toward bringing the *people, as a whole*, up to the point of sustaining and approving all measures for good mental health, hygiene, and prevention. To the medical mind the ignorance is stupendous as yet. One need not cite the suicidal action of alcoholics to confirm this, nor the frequent upholding of gross defectives as being sound in mind, so often noted in work among the insane. This paper itself, indeed, is but an attempt toward educating people to sustain firm measures, because bringing to them a clearer insight of bad effects.

To avoid leaving this as a mere theoretical treatment of the subject, let me consider a few facts. Many people will say of a defective, "he got this from his father or mother," but will not think to take the next fairly logical step—"his father or mother ought not to have married." Among domestic animals no such degeneration of stock is allowed. How many of us will realize how forcibly these things press upon us? How few of us realize that in the last ten years about five thousand people were discharged from the insane hospitals of this State alone, about two thousand of whom were already married, and most of the rest free and of age to marry. Probably during the ten years the institution-insane alone have become parents of five thousand children, 25 to 50 per cent. of whom will probably before death show some defectiveness. This is but one item. They were parents of about an equal number before becoming insane. There are also the insane who have never been committed to an institution, probably numbering one thousand in this State at any one time. There are the imbeciles and epileptics of marriageable age, living outside of institutions, numbering many hundreds, and probably another thousand. And what shall we say of such of the graduates of reform-schools as are perverts, of those having gross nervous diseases, of those in the later stages of consumption, of the grossly inebriate, as well as the ill-cared-for children of paupers, of prostitutes, and the many illegitimate births, with their uncertain and often impaired inheritance. The census of 1880 claimed about one in every one hundred people of all ages as among the defective, delinquent, and pauper classes. This would make a proportion among the adult persons of about one in every seventy-five, and even then would include only the grossest cases. Is not here the largest known field for effort?

Under the second subdivision of the subject, that of education, comes subordinately the hygienic education of children and of adults who are predisposed. We cannot give much of detail. It embraces, indeed, all ways of living. A few leading ideas may be mentioned.

1. Early book-education should not be forced; let the child grow up and absorb its education by contact. It is stability of character and ability to do that the child needs, not the hot-house growth of memorized data.

2. Repress the too often excitable or emotional disposition toward a quiet, steady control of self. Do not encourage any one to be a prodigy. Extreme brightness in some one way may mean an unbalance. It is not the enduring element.

3. A country life and an outdoor life for a child tend usually in the right direction. All seclusion and sedentary habits are to be avoided.

4. Educate the child freely, rationally, and plainly against the evils of dissipation, of alcoholism, and of all excesses. Alcoholism especially has a distinct tendency toward both physical and mental impairment. Of course, the parent is the natural educator of the child, and in proportion as the parent is unbalanced, erratic, unstable, hysterical, alcoholic, or of other mental defect, the tendency will be to perpetuate carelessly the defectiveness. To quote from J. Madison Taylor concerning imbeciles, "In a large proportion of cases the parents are themselves mentally incompetent. They are certainly rarely fit to grasp rightly the spirit of the inquiries." This is only to be met finally by the general culture of an enlightened public opinion, as before outlined.

5. Beside such causes as above considered, causes such as malnutrition, blood-changes, fevers, toxic elements, and ways of living are more vaguely acting causes calling for medical study and an education in physiology or physical life, as well as in the more and mental influences above.

Summarizing, then, we find that to those to whom most peculiarly belongs the name defective we have:

1. A gross form of mental feebleness can be produced by head-injuries or in later life by brain-changes like those of hemorrhage or abscess of the brain, and in senile life atheroma, atrophy, and general senile recession.

2. In very early life such causes as severe typhoid or scarlet fever can in a few cases produce permanent feebleness of mind, however, acting upon a predisposition.

3. Under heredity we may have (*a*) one or both parents insane, imbecile, epileptic, paralytic, eccentric, hysteric, choreic, or with other nervous or mental defects, or (*b*) one parent may be syphilitic, consumptive, alcoholic, or Brightic, and the nervous system thus impaired will show an impaired nervous system in the children of varying type, or developing into defects the form of which seems largely a matter of seeming chance.

Under headings one and two our preventive ideas do not very thoroughly apply, but these do not make up a very high per cent. of our total cases. The third class is that to which we may apply our effective study. We advocate, first, legal measures controlling or preventing the marriage of the grossly defective ones; secondly, hygienic and general education which shall hinder the development of the predisposed traits and help people to avoid the effects; and, thirdly, the education of the popular masses to sustain and support preventive measures as advocated.

In conclusion, concerning legal measures, just a note. It has been said that all men are "free and equal," but the fallacy of this is now quite well known. We are not free to do that which will interfere with other's freedom or well-being, and the marriage of epileptics certainly does just this to the offspring. I feel that by such measures we strike at the root of the evils, while by nursing and liberating the defectives we merely try to bend and direct and make healthy the branches and often perpetuate the defectiveness. I cannot think that by multiplying words or by rhetorical effects I can add to these plain statements, which I hope are honestly, if too bluntly, stated. I therefore leave the subject with you.

CLINICAL MEMORANDA.

BELLADONNA-POISONING WITHOUT DILATATION OF THE PUPILS, CAUSED BY A BELLADONNA-PLASTER.[1]

BY DOUGLASS W. MONTGOMERY, M.D.,
PROFESSOR OF DISEASES OF THE SKIN, MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA; CONSULTING PHYSICIAN FOR DISEASES OF THE SKIN AND PATHOLOGY, GERMAN HOSPITAL.

I ONCE ran across the following case of belladonna-poisoning, which had not the usual prominent symptom of dilatation of the pupils, and this peculiarity, together with some other circumstances of the case, put me so on the ragged edge of doubt for a few hours that the lively impression of the incident will probably never leave me.

On April 2, 1891, about 10 o'clock in the evening, I was called to see a patient who had consulted me several times before on account of rheumatic pains, cramps, and various minor ailments.

He was a large, fleshy man, aged sixty-seven years,

[1] Read before the San Francisco County Medical Society, December 10, 1895.

a good eater and drinker, very well preserved, and had a distinct murmur with the first sound of the heart, heard loudest at the apex. Sometimes he had dizziness while walking on the street, and occasionally pain and numbness in the fourth and little fingers of the left hand, a symptom that is not infrequently associated with valvular disease. In no other respect, however, did he seem to suffer from his cardiac trouble, for the equilibrium of the blood-current seemed always well maintained, and if there was any hypertrophy it must have been trifling.

As I said before, I was called in to see him on this particular evening, and I found him with a flushed face and his tongue so hard and dry that it felt as it sometimes does in extreme cases of diabetes. There were constant attempts to swallow, and he had a quickened and rather stormy pulse and increased respirations. His speech was rather thick on account of the dryness of the tongue and mouth, and he was a little "rattled" in his ideas, but rational enough to give an account of himself. He said he had felt this coming on just before dinner, and he attributed it to some whiskey and quinine which he had taken at a bar during the afternoon. It happened that just at that time this way of taking whiskey was the fashionable "tonic" in the down-town drinking-resorts, and was drunk by a large number of people who wished to be in that particular "swim." I knew of and had seen the erythema sometimes caused by quinine, and also knew that whiskey thickened the tongue and jangled the ideas out of tune, but neither of these drugs nor their combination seemed to fit the symptoms in the present case. Atropine- or belladonna-poisoning ran through my mind, but this idea was dismissed because the pupils were not dilated, and they did not dilate during the entire trouble. Furthermore the whiskey and quinine were taken at a bar, not in a drug-store, so that there was little chance of a mistake in dispensing, and he said he had not taken any other drug during the afternoon, and of this fact he was positive.

Although he had every appearance of having a very high fever, yet his temperature was normal; but then febrile affections do occur without a thermal rise. I went over his chest carefully to exclude pneumonia, nor could I find anything else to account for his condition. All this was not very satisfactory, but the facts as I saw them were: A man puffing away at a fairly high rate, with a stormy, accelerated pulse, a dry, hard, furred tongue, a dry, reddened, but not hot skin, a flushed face, constant efforts to swallow, no rise of temperature, and no dilatation of the pupils.

Having determined to await further developments, I left him, promising to be back early the next day.

I was called again at 2 o'clock in the morning, those who were watching him becoming very much alarmed. He was now frankly delirious, although the delirium was not of a dangerous character. He was very restless, picking at the bed-clothes, constantly attempting to get out of bed, and mumbling incoherently and rapidly about a gold-mine in which he was interested. He had evidently grown a great deal worse during the few hours I had been absent. He was not suffering from diabetes, for there was no sugar in his urine, and there had been none in any of the examinations that had previously been made of it. Nor had I ever found any albumin. He used to pass only from a quart to forty ounces of urine a day, excluding that passed at stool, but he always perspired very freely, which would account for the somewhat diminished quantity. Bright's disease without albuminuria does occur, and the heart-lesion, the diminished quantity of urine, and the patient's habits made me watchful in this regard. There was no urinous odor on his breath, however, and the general symptoms did not tally with those of a case of uræmic delirium.

While sitting on a chair watching the patient and thinking what in the world could be the matter with him, it suddenly occurred to me that I had told him to put a belladonna-plaster over one of the numerous pains and aches he used to complain of. I almost automatically walked across the room and felt under his shirt, finding an immense belladonna plaster twenty inches long and six inches broad over the left side of the chest. This was quickly pulled off, the skin well washed, and a hypodermic of morphine given.

He soon recovered and was able to go about his ordinary business in a few days.

He gave the following account of how it all happened: He had worn smaller pieces of belladonna-plaster over the left side of the chest for quite a long time, and had frequently suffered from dizziness and a dry, uncomfortable feeling in the throat. The dizziness was supposed to be owing to functional derangement of the liver, and the dryness in the throat to a pharyngitis. The afternoon of the evening on which he was taken ill he went to a drug-store and asked for a good, big piece of plaster. They said they had some in just fresh, and they cut off as large a piece as he wanted. Having secured the plaster he went to the baths and took a piping-hot soak, and applied the plaster to the actively perspiring, freshly washed skin. Before dinner his mouth was already disagreeably dry and his throat constricted, but he did not heed it much. The other symptoms followed as they are related.

Belladonna, or its alkaloid atropia, is used so much in medicine, and the drug acts so energetically on human beings, that cases of poisoning by it cannot be said to be rare. Poisoning by the application of a plaster is, however, undoubtedly not a frequent occurrence, but its possibility ought to be borne in mind.[1] This case was peculiar in that there was no dilatation of the pupils, an event so rare that its absence would justify entirely overlooking the fact that it was a case of

[1] Pye-Smith mentions a case of belladonna-poisoning under the care of Mr. Hilton, "caused by the application of a large belladonna-plaster in a woman, who must, one supposes, have been more than commonly susceptible." (Diseases of the Skin, by Pye-Smith, p. 180.)

In one case 100 milligrammes (about 1½ grains) of atropine caused death by being absorbed through a vesicated surface. (Lehrbuch d. Intoxikationen, von Dr. Rudolf Kobert, Seite 606.)

Crocker mentions the case of a man who wore a belladonna-plaster for a week and then took two seven-drop doses of the tincture, causing his hands and feet to become swollen, red, and tense. (Diseases of the Skin, by H. Radcliffe Crocker, M.D., p. 327.)

Ernest F. Maddox has also reported a case of poisoning by a belladonna-plaster (Amer. Journ. Med. Sciences, vol. cvi. p. 572). The pupils were no more dilated than is frequently the case in myopia.

belladonna-poisoning at all.[1] But if the dilatation of the pupils had been present, and the fact of its being belladonna-poisoning forced on one, so to speak, even then one might not think of the possibility of its being caused by a belladonna-plaster.

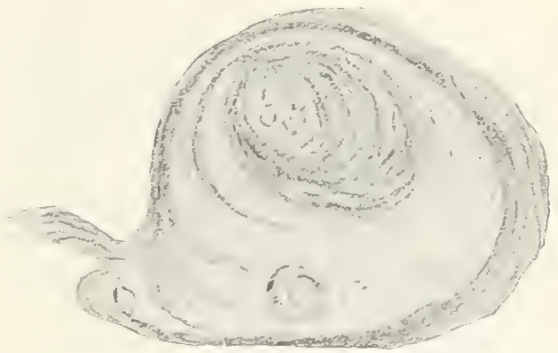
If I had then known of that very simple way of demonstrating belladonna-poisoning by dropping some of the patient's urine in the eye of the family cat, the patient might have been saved a risk and I a great deal of worry.[2]

REPORT OF "A CASE OF EPITHELIAL CANCER OF THE NOSE OF THREE YEARS' STANDING;" ITS TREATMENT AND CURE.[3]

BY CHARLES R. WEED, M.D.,
LARYNGOLOGIST AND RHINOLOGIST TO ST. ELIZABETH'S HOSPITAL, UTICA, N. Y.; MEMBER OF THE ONEIDA COUNTY MEDICAL SOCIETY, ETC.

SEPTEMBER 14, 1894, Mrs. H., seventy-five years of age, was sent by Drs. Quin and Bergess, of this city, as a case of epithelioma, which, on examining carefully, I confirmed. The characteristic "concentric globes or epithelial nests" presenting in microscopic section, I at once proceeded to clean the ulcerated and broken-down surface carefully and thoroughly, and though advising curettage, it was decidedly objected to by the patient. The seat of the disease was on the right nasal ala near the junction of the cartilage with the right bone of the nose, and extending in its course to within one-fourth of an inch of the internal canthus of the right eye. As destructive action had advanced under the scab which covered it I proceeded to use trichloracetic acid, being particular to cauterize thoroughly every portion of the cancerous mass, first using a 10 per cent. solution of cocaine to relieve the pain. I then gave my patient a solution of zinc chloride, ten grains to the ounce, with directions to keep the surface wet with the same and to see me the following day. The disease was of three years' standing, the woman emaciated, poorly nourished, and full of "Irish obstinacy," so much so that she would not take any internal medicines, and other doctors had prescribed ointments, etc., galore—of course, unavailingly.

This case at the sixth visit began to show slight improvement. The slough from the acid was removed and effort made to induce granulation. For months it was "up and down," and when after healing two-thirds of the sore pearly nodules would appear in the upper portion and have to be destroyed, necessitating more patience and care. I continued my treatment of the case, varying the dressings but slightly and depending *entirely* upon the zinc-lotion and the acid cauterization. My work has been rewarded with success. There has been perfect healing, and with the exception of a slight depression the skin is unbroken. The original size of the cancer was one inch by three-fourths of an inch, and she had been discouraged by everybody.



As I took the case (a charity one, by the way) for the purpose of experimentation, I feel positive that if this treatment is followed under similar conditions success will be assured. Of course, the administration of arsenic in these cases I should consider beneficial; but, as heretofore stated, "my old woman" would have none of it.

The trichloracetic acid I consider the best local caustic, and in this case unquestionably was the curative agent.

I present this case for your consideration.

226 GENESEE ST., UTICA, N. Y

[1] It must not be forgotten that this was a case of chronic poisoning, for the patient had worn belladonna-plasters, although not such large ones, for a very long time, and Sabatini (quoted by Kobert) draws attention to the fact that the drug, after a time, ceases to act on the salivary glands, the heart, the intestine, and last of all on the pupil. (Lehrbuch d. Intoxikationen, von Rudolf Kobert, Seite 610.)

Dr. L. Lewin draws attention to the fact that there can be belladonna-poisoning with only moderately dilated pupils. (Nebenwirkungen d. Arzneimittel, p. 221.)

[2] Mentioned by Prof. H. C. Wood in his lecture on belladonna. (The Boston Medical and Surgical Journal, July 13, 1893.)

[3] Patient presented before Oneida County Medical Society quarterly meeting, July, 1895.

MEDICAL PROGRESS.

Infection through Books —At a recent meeting of the Société de Biologie, DU CAZAL and CATOIN (*Münchener medicin. Wochenschrift*, 1896, No. 1, p. 22) detailed the results of an investigation to determine whether books were capable of transmitting contagious diseases. The streptococcus, the pneumococcus, the diphtheria-bacilli, the tubercle-bacillus, and the typhoid-bacillus were thus studied. Animals inoculated with cultures prepared from books contaminated with the products of the various conditions in which the organisms named were found developed the given affection. It is thus necessary to practise disinfection of books that have been used or in any way contaminated by persons suffering with infectious diseases.

An Analysis of Eighty Cases of Lithotrity.—At the recent French Congress of Surgery, ALBARRAN (*Ann. d. Malad. d. Org. Gén.-Urin.*, 1895, No. 12, p. 1079) presented a statistical analysis of 80 cases of lithotrity. Seventy-six were in males, 4 in females (1 in a girl of ten years). Of the calculi, 46 were phosphatic, 29 uric acid, 4 urophosphatic, and 1 oxalic. Of the patients, 20 were older than seventy years, and 7 had reached or passed seventy-eight years. The oldest was eighty-four years, and presented aortic insufficiency; the operation was performed without anæsthesia, and the calculus removed weighed 400 grains. The largest stone crushed measured 2.5 inches in its longest diameter, and weighed 2.5 ounces. In two-thirds of the cases the bladder was

infected, and in many the prostate was enlarged; in several pyonephritis existed. In 8 cases the operation was performed without anæsthesia, sometimes because of facility of performance and small size of the stone, and at other times because of contraindications to anæsthesia. Recovery ensued in all cases but one, in which death resulted from anæmia.

The Renal Changes of Diphtheria.—REICHE (*Centralbl. für innere Medicin*, 1895, No. 50, p. 1209) reports the results of a study of the kidneys in 85 fatal cases of diphtheria observed prior to the antitoxin-period. Thirty-eight of the cases had been in males and 47 in females. Fifty-two were under five years of age, 23 between six and ten years. In 22 death took place between the 2d and 5th days, in 36 between the 6th and 10th days, in 27 between the 11th and 24th days. Tracheotomy had been performed in 58. Forty-seven presented lobular pneumonia of varying extent. In many cases the trachea and bronchi were involved in the diphtheritic process; in 14 the gastric mucous membrane, in 8 portions of the œsophagus, and in 1 a portion of the ileum.

The kidneys presented no constant or characteristic naked-eye appearance. Microscopically, changes in parenchyma, interstitial tissue, and Malpighian bodies were visible. Those in the parenchyma were the most pronounced and assumed two main types. In all there was cloudy swelling of the epithelium and later fatty degeneration. A smaller number of cases presented coagulation-necrosis. In 44 cases inflammatory proliferation of the interstitial connective tissue was found. In all instances the changes were most pronounced in the cortex. The Malpighian bodies constantly presented alterations, though of varying degree. All of these changes are attributed to the action of the toxins generated at the seat of the diphtheritic process, and thence absorbed into the circulation. The liver was affected in a similar way, but in a much smaller number of cases and in slighter degree; the pancreas only exceptionally. No relation, however, could be established between the character and extent of the diphtheritic process and the secondary changes in the abdominal viscera.

Pseudo-bulbar Paralysis in a Child Three Years Old.—At a recent meeting of the Society of Pediatrists of Moscow, KYSSELE (*Presse Médicale*, 1896, No. 3) reported the case of a girl apparently normal at birth except for pronounced flexion of the fingers and toes. It was at once observed, however, that the infant suckled with difficulty, and later that it failed to protrude its tongue. At the age of about a year, following an acute illness lasting three months and diagnosticated as typhoid fever, the child presented a condition of weakness, with difficulty in deglutition. It had never spoken. On examination, at the age of three years, the child protruded its tongue with difficulty. There was copious salivation and a disagreeable odor exhaled from the mouth. The bony skeleton and the musculature were well enough developed. There was no evidence of rhachitis, although the state of the nutrition was below par. The mucous membranes presented a normal tint. The gums were swollen and hyperæmic, and bled readily. No lesion of the viscera could be discovered. The sternum was deeply depressed with each inspiration. Hearing and vision were normal. There existed simple nonatrophic paralysis of the muscles supplied by the two inferior branches of the facial nerves, involving especially the orbicularis oris; those supplied by the upper branches were normal. The hypoglossus was paretic on both sides. Respiration was free, but phonation was impaired. The extremities were rigid, but the electric reactions were preserved. The cutaneous reflexes were generally increased, and the tendinous reflexes also, especially in the lower extremities. The feet occupied a position of equinovarus. The little one could stand erect if supported, but it was unable to walk. Urine was passed incontinently.

Successful Total Extirpation of a Gravid and Myomatous Uterus.—CAMERON (*British Medical Journal*, No. 1823, p. 1414) has reported the case of a woman, thirty-six years old, in the fifth month of her first pregnancy, whose abdomen was greatly distended. Eight years previously the patient had noticed by accident a swelling in the left iliac region, about the size of a hen's egg, which for a month or two increased in size slightly, then ceased growing and remained stationary till she became pregnant. The legs and thighs were œdematous, and some dyspnœa existed. There was no difficulty in micturition, but the bowels were constipated. Lungs and heart presented no abnormality. Milk could be expressed from the breasts. The abdomen was greatly distended, presenting the appearance of pregnancy at term. It measured thirty-seven inches in circumference at the level of the umbilicus. On palpation, a large, smooth, round, hard swelling was found in the left side of the abdomen, crossing the middle line and being continuous with a swelling on the right side, from which, however, it was separated by a sulcus. The swelling on the right side was elastic in consistence, but two or three hard, rounded nodules could be distinctly made out on its anterior surface. Over it the uterine souffle could be heard, but the fœtal heart-sounds could not be recognized. On vaginal examination the whole cavity of the pelvis was found to be filled with a hard mass, impacted in it and continuous with the tumor above. The uterus appeared to be very much drawn up. Cœliotomy was undertaken, and when the abdomen was opened a large, irregular tumor was encountered, the left portion consisting of an interstitial myoma, the right of the distended uterus. In addition, implanted upon the upper and posterior uterine walls, were several subserous myomata, varying in size from a walnut to an orange. Through an incision in the anterior wall of the uterus a five months' fœtus was removed, which was perfectly formed and had evidently been dead only a short time. The placenta was well developed and was easily detached. An elastic ligature was passed around the uterus and tumors as close as possible to the cervix and secured. The uterus and tumors were cut away and the uterine and ovarian arteries were ligated. The ovaries and tubes were also removed. The tumor blocking up the pelvis was with some difficulty freed from adhesions, drawn up, and enucleated. The peritoneum was stitched round and round with catgut ligatures to the mucous membrane of the vagina. These ligatures were then drawn down into the vaginal canal and the abdominal wound was closed with silkworm-gut sutures. The patient made a good recovery, being dismissed perfectly well in the seventh week after the operation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

IN THE MATTER OF IDIOTS.

THE State Commission in Lunacy of New York have so construed the amended Constitution that a class of inmates of the State Hospitals for the Insane are liable to be left without proper care and supervision. The Constitution provides that there shall be "a State Commission in Lunacy, which shall visit and inspect all institutions . . . used for the care and treatment of the insane (not including institutions for epileptics or idiots)." The Lunacy Commission construes this exemption of institutions from its visitation and inspection to mean that the idiots at present in the State hospitals must be removed, and accordingly a circular has been issued by the Commission to the superintendents, "In the matter of Idiots," directing them to notify friends and county authorities that they must forthwith remove those idiots for whose care the latter are responsible. The superintendents are now engaged in informing the county officials of the names of idiots in their hospitals who must be removed under this order of the Commissioners. This removal of idiots from the State hospitals means that they are to be returned again to the poor-houses from which they were, for the most part, so recently transferred under the provisions of the State Care Act.

The result of this action of the Commission has created great excitement in many counties, owing to the disturbances which these so-called "idiots" create in the poor-houses, and the entire want of adequate facilities for their proper care. In Kings County the Charities Commission has flatly refused to receive these "idiots" unless the Superintendent of the State hospital certifies that in each case the person is not insane. The Commissioners have taken that position under the instructions of the State Board of Charities, which has supervision of the poor-houses of the State. Meantime, this most helpless and pitiable class of dependents, for which the vaunted State Care Act was believed to have done so much, by removing them from the poor-houses, have no legal status in the State or county institutions. The insane idiots of New York are like the bat in the fable, which the beasts would not receive because he was a bird, and the birds because he was a beast.

The position taken by the Lunacy Commission seems hardly tenable in view of all the facts. The new Constitution simply prohibits that body from visiting and inspecting institutions for idiots. It in nowise forbids the reception and retention of persons duly adjudged insane in the State hospitals, though they may be otherwise classed as idiots. On the contrary, the law prohibits all other institutions from receiving and retaining them in custody except the State hospitals and institutions licensed by the Lunacy Commission for the care and treatment of the insane.

A fair construction of the Constitution and the lunacy laws would seem to lead to two conclusions: (1) that the Commission cannot officially visit and inspect institutions for idiots, and (2) that the State hospitals must receive for care and treatment all persons taken to them with duly prepared papers adjudging them insane. Nor are these two legal requirements incompatible, for while the Lunacy Commission is prohibited from visiting and inspecting poor-houses, the insane of the poor-houses must be removed to the State hospitals. So it has followed, under the operations of the State Care Act, that among the insane persons found in the poor-houses were some who are now called "idiots." They were transferred to the State hospitals as insane, and were by them duly received, registered, and held in custody. The fact that subsequently

the Constitution limited the visitations and inspections of the Lunacy Commission would not seem to change the position of a certain class of insane in the State hospitals. It would be quite as consistent for the Commission to order the removal of all insane blind or deaf from these hospitals, because that body is not allowed to visit and inspect the institutions for the blind and deaf.

THE ECONOMIC ASPECT OF CERTAIN MUTILATING OPERATIONS UPON MEN AND WOMEN.

ALLUSION is made to those operations by which not only are important organs removed from the body, but by which the body is also forever rendered incapable of fulfilling one of the most important functions of life—that which pertains to reproduction. These organs, the ovaries in women, the testicles in men, are essential to the propagation of species; without them there can be no reproduction.

There is no occasion for argument in all those cases in men and women in which these organs are hopelessly—so far as human knowledge and judgment can determine—diseased. For such individuals, reproduction being out of the question, and the diseased organs a menace to comfort if not to life itself, there is no more impropriety in their removal than there is in the removal of any other structure or tissue which is injurious to the body at large. There are other cases in which the removal of the organs is more or less debatable, as in cases in which one ovary is hopelessly diseased and the other only slightly so; also many of the cases in which removal of the testicles is advocated for the relief of enlargement of the prostate gland. One may err in such cases by either radical or conservative treatment. Still further, there are cases in women in which the ovaries are sound or sufficiently so to enable menstruation and ovulation to continue, and in which the ovaries are removed because of some serious difficulty in structure or function in some other part of the body. Such conditions as fibroid tumor of the uterus, obstinate and intolerable dysmenorrhœa, the severer degrees of chronic endometritis, etc., are examples of disease in which the mutilating operation referred to has often been followed by the most satisfactory results. It must not be forgotten that in the great majority of the cases which have been considered the individuals are incapable of reproduction, whether the diseased organs are removed or not. Removing the organs does not change the sterile condition, but it frequently does so improve the patients' condition in other respects that they are no longer a burden to society, but become able to take care of themselves or even to assist others. For all such cases the operation represents a decided economic gain. As to the others in this group in which organs only partly diseased are sacrificed, or those which are not at all diseased are sacrificed for the advantage of the body at large, no doubt mistakes are sometimes made. In the anxiety which some men seem to have to roll up large series of cases we believe they often operate prematurely, not to say without just cause. This barbarous *furor secandi* which consumes some operators is like the savage's desire for scalps, and does not always represent such work as would bear close scrutiny in all its details. Nowadays, when the world is so full of men who are removing ovaries by hundreds and uteri by scores, it is well to make some inquiry as to the antecedents of both the operators and their patients should our opinion be asked as to the justifiability of this unsexing by wholesale.

It is unbecoming to judge of any man's work without knowing the details, but we cannot help the belief that among the thousands and tens of thousands of women who have been unsexed in the last twenty years the unnecessary operations have formed no inconsiderable percentage, and thus has occurred a great economic loss, not only in the number of fatal cases, chiefly unreported, of those who were more or less valuable elements of society, but in the check to population by the sterilization of the many who were capable of bearing healthy children and properly rearing them.

We are not of the number of those who believe that the chief object of a woman in life is to bear children. Ability to do so is, however, of great importance, and there are probably few physicians or surgeons who would care to marry one whom they knew to be without this ability.

For obvious reasons, it need not be feared that the operation which has proved so effective for the relief of enlarged prostate will ever become as popular as ovariotomy, common though enlarged prostates are.

There is another side of this question relating to the cases of severe disease in men and women, which require removal of the essential generative organs, in which the general practitioner in charge

is at fault, because he fails to appreciate the gravity of the situation, temporizes and palliates until an abscess ruptures internally or general septicæmia occurs, or a crisis of some other character arrives, the result of which is that the slenderest possible chances of relief by surgical measures remain, and the patients either die without an attempt being made to help them, or in consequence of an operation, in which case the last man to see the patient usually gets the blame. Such procrastination in these times is seldom justifiable. There are too many available men in most communities who are skilful in handling such cases if given reasonable conditions for success, to warrant the general practitioner in conducting them unaided until the time for interference has gone by. This also represents economic loss from another point of view.

We now come to an aspect of the subject which will doubtless excite opposition, and may seem inconsistent with the spirit of the remarks which precede. It is not the first time that it has been broached by us or by others. It is a subject which must come up for agitation, as a matter of scientific and economic importance, and will be settled *pro* or *con*, we believe, in the near future.

It concerns the sterilization of the irreclaimably bad in the community, both males and females, for the protection of the community, by removing at least one potent source of supply. It is idle for anyone to claim, in these times, that heredity does not exert a most powerful influence upon the physical, moral, and intellectual development. Men or women with bad characteristics will breed their like. Thieves, harlots, and drunkards consort together, for they have similar tastes. Add to heredity the vicious environment to which the children of such parentage are subjected, and we can hardly fail to have criminal traits and tendencies continued and intensified. The well-known statistics which were compiled a few years ago, and which traced the history of a woman of vicious propensities, who finally brought up in an almshouse, showed in the children and grandchildren, many in number and invariably (we believe) criminal in tendency, what an enormous load society takes upon itself in allowing such depraved beings to reproduce their kind indefinitely. Communities offer bounties for the destruction of noxious beasts and vermin, and yet offer no resistance to the reproduction of elements far more dangerous than these. From the humanitarian standpoint such sterilization is robbed of objections which a few years ago could have been urged against it, for it can be done painlessly and with almost no danger to life.

Naturally it would have greater terrors to men than to women, especially to young men, by whom the greater number of crimes are committed. It should be applicable only to incorrigible offenders; that is, to those who have been sentenced to prison two or three times for serious crime, or to those who are guilty of crimes which are particularly revolting and shameful. It would probably act as a deterrent to the commission of many crimes, not alone from the sense of personal loss and defect involved, but from the disgrace which would attach to it and the exposure to ridicule.

It would certainly be offered as a substitute for lynching in those parts of the country where rape and similar deeds of violence are said to abound, and might tend not only to diminish the number of such lawless procedures, but also tend to diminish the crimes which evoke lynching, the latter being manifestly a failure in that respect.

Of course, the scope of this article would prevent us from going into the details appertaining to the suggestions which have been made.

The matter must be treated as any other pathological-sociological subject would be treated, and discussed from its scientific as well as from its sentimental bearings.

BACTERIOLOGY.

UNDER THE SUPERVISION
OF
WILLIAM H. PARK, M.D.

THE PRESENT STATUS OF THE USE OF BACTERIAL CULTURES FOR THE DIAGNOSIS OF SUSPECTED DIPHTHERIA.

THE making of a true diagnosis in every case of suspected diphtheria is at the present time not only of importance for the public health and for prognosis, but also as a guide to the use of the antitoxin in treatment. That we may judge fairly the exact value and meaning of a bacterial examination let us consider carefully the nature of the information which we derive from the examination of the bacteria on the coagulated blood-serum after a stay of twelve to fourteen hours in the incubator after its inoculation with the throat-secretion or exudate from a suspected case of diphtheria.

The facts upon which the use of cultures for diagnostic purposes is urged are as follows:

1. That in all cases of diphtheria the diphtheria-bacilli are present.

2. That those cases in which the diphtheria-bacilli are absent, not only do not themselves develop the characteristic lesions of diphtheria, but never communicate true diphtheria to others.

3. That many of the less characteristic cases of diphtheria and pseudo-diphtheria are so similar in appearance, symptoms, and duration that it is impossible to separate them by any other means than through cultures.

4. That the throats of many healthy persons who have been in contact with diphtheria or with articles infected with the bacilli become infected, and that although they may never develop diphtheria, yet their throat-secretions are equally as dangerous as those of convalescent cases in whose throats the bacilli persist.

5. That the examination of cultures made upon solidified blood-serum under the proper conditions forms, with few exceptions, a reliable method of determining whether the diphtheria-bacilli are present or absent in the suspected throat.

The very nature of the bacterial examination of the growth on the coagulated blood-serum suggests that it must to a certain extent be incomplete.

To be of practical value to the physician the report must be received within twenty-four hours of the time of the making of the culture. This necessitates that the diphtheria-bacilli be differentiated from all other bacteria simply upon the examination of the stained cover-glass preparation from the original serum-tube. Anyone who is familiar with bacteriology knows that this is impossible. Very fortunately, however, there are very rarely any other bacilli in the throat which both grow upon blood-serum and have the same staining and morphological characteristics as the diphtheria-bacilli.

This practically excludes the error of confusing the virulent diphtheria-bacilli with any other bacteria except two forms—the so-called pseudo-diphtheria-bacilli and the non-virulent bacilli.

The pseudo-diphtheria-bacilli present sufficient peculiarities to be separated from all but a few of the forms of the less characteristic diphtheria-bacilli. The virulent and non-virulent diphtheria-bacilli present, however, identical appearances and cultural peculiarities and can only be separated by animal inoculation.

These non-virulent bacilli are most abundant in those places where diphtheria has long been prevalent, and are, in fact, virulent bacilli which have lost their virulence.

These bacilli, like the pseudo-diphtheria-bacilli, are, so far as we know, incapable of causing disease. They exist in about one per cent. of the throats of persons living in great cities.

The practical difficulty which the non-virulent bacilli cause in the use of cultures for diagnostic purposes is apparent. If a culture from a suspected throat which presents no characteristic lesions contains bacilli looking like diphtheria-bacilli, we cannot positively state whether they are virulent or not. The amount of probability in any case would depend upon the prevalence of the non-virulent forms in that city or neighborhood. Thus, to give an example:

If there develops in a throat in which non-virulent diphtheria-bacilli exist a simple follicular tonsillitis, cultures would contain bacilli identical in growth with the virulent germs, and the report of such an examination would indicate that the case was one of mild diphtheria. The bacilli in this case, however, would still be non-virulent, and have no connection with the tonsillitis. Another limitation in the value of cultures is that they show only in the roughest kind of a way how many bacilli are in the secretion of a suspected throat; and, on the other hand, they do not absolutely prove that the bacilli are entirely absent from the upper air-passages because they were absent upon the limited portion of mucous membrane touched by the swab.

This is really of great importance in laryngeal diphtheria, for it has been frequently found that the bacilli were at times scant or absent in the pharynx while abundantly present in the larynx and trachea.

To sum up, therefore, we may say that if a culture made under proper conditions contains no bacilli similar to those of diphtheria, it may be concluded that the throat from which it was made contained no diphtheria-bacilli, and that the disease was not diphtheria. If, however, the culture contains bacilli having the characteristics of the diphtheria-bacilli, we can only conclude, unless we wait for animal inoculation, that the bacilli are in all probability virulent. The degree of this probability in any given case will depend greatly on the history of exposure and the lesions present.

In view of this doubt, wherever possible the virulence of the bacilli in the mildest cases should be tested, and where this is impossible health-departments may find it wise to arrange it so as to allow the physicians themselves to exercise a certain amount of responsibility in determining whether cases which have no characteristic symptoms, and yet show bacilli in their cultures, should be treated as diphtheria or not. Undoubtedly, if this were done, a certain number of mild cases of diphtheria would be freed from strict isolation and some harm result; but, on the other hand, physicians would more freely seek the aid of cultures in these light cases, and also co-operate more heartily with the health-authorities. Thus in the end many more of the lighter cases of diphtheria would be partially isolated and receive, when necessary, injections of antitoxin for treatment or immunization.

THE POSSIBILITY OF THE MAINTENANCE OF ANIMAL LIFE WITHOUT BACTERIA IN THE ALIMENTARY CANAL.

SOME ten years ago Pasteur appended to a publication by Duclaux a note in which he expressed his deep interest in the question of a possible relation between bacterial life and animal nutrition. He had often, he said, in his talks with young scientists, spoken of the interest which would attach to attempts made to nourish a young animal (rabbit, guinea-pig, dog, or chick) with food completely deprived of bacteria. He was inclined to believe that life might be found impossible under these circumstances, and suggested that if this point were once proved, further experiments might be undertaken in order to determine the organism, or group of organisms, best suited for aiding in the normal processes of digestion. These suggestions of Pasteur attracted considerable attention, but, as is too often the case, a number of individuals, failing to distinguish between a mere statement of opinion and a proved fact, took it for granted that the presence of bacteria in the alimentary canal was absolutely essential for the maintenance of animal existence.

Nencki showed that the digestive ferments by themselves, in the absence of bacteria, are able outside the body quickly and easily to transform food-stuffs into substances ready for absorption, and the alterations which certain substances, the albuminous, for example, undergo through bacterial action, are at first similar to those which result from the action of the digestive ferments. But here the similarity stops, for the end-products of bacterial decomposition are quite different, food-stuffs under their action being split up finally into aromatic acids, volatile fatty acids, phenol, kresol, indol, skatol, carbon dioxide, hydrogen, methane, and hydrogen sulphide; *i. e.*, into substances which no longer possess any value as foods, and may even, under certain circumstances, prove injurious to the individual in whose alimentary tract they are manufactured. The only possible way of settling the question, however, once it had arisen, was to submit it to actual experiment, and this has recently been done by Nuttall and Thierfelder, in the Hygienic Institute of the University of Berlin.

The employment of the chick, as suggested by Pasteur, was found to be inexpedient, since a certain number of hen's eggs are always infected. The animal found by the experimenters to be most suitable was the guinea-pig obtained by Cæsarean section. This animal was chosen on account of the ease with which it can be reared on undiluted cow's milk, and also on account of the independence which young guinea-pigs manifest from the moment of birth.

The apparatus devised for the reception of the young guinea-pig, after removal from the body of its mother, though somewhat complicated, is relatively simple when one considers the many difficulties which had to be met. A full description of it would be out of place here, but it is of interest in reading the original article[1] to find how each detail was gradually worked out. Suffice it to say that the handling and feeding of the animal, the method of supplying it with air, the removal of excreta, etc., were all finally arranged, so that all danger of bacterial contamination was obviated. It is worth noting that the main difficulty encountered was not in the bacteriological technique itself, but in the disposal of excreta, so that the moisture of the latter should not condense upon the bell-jar or upon the animal under experiment; this drawback was finally overcome by allowing the excreta to fall into water covered by a layer of oil.

The Cæsarean section on the mother guinea-pig had to be done, of course, under strictly aseptic precautions, and it was found that failure of the experiment through bacterial contamination was most

[1] Ztschr. f. Physiol. Chemie, Bd. xxi, Heft 2 u. 3, Nov. 1895.

likely to occur between the time the abdomen was opened and the moment in which the animal was safely enclosed within the apparatus in which it was to be kept.

At the end of twelve hours the animal was fed with sterilized milk, which was given afterward every hour, night and day. By the eighth day after birth the guinea-pig had taken 330 cm. of milk, and appeared normal, looking as healthy and active as the control guinea-pigs removed from the uterus of the same mother and reared in the ordinary way. At the end of this time the animal was killed, and the body opened aseptically. Neither in cover-slips nor in cultures, aërobic nor anaërobic, from both the small and large intestines, could a single bacterium be demonstrated. The experiment proves, therefore, that a guinea-pig can live at least for eight days on sterile milk without the presence of any bacteria in its alimentary canal. Whether or not an animal can live on a vegetable or a mixed diet under similar conditions has been left for further experiment to decide.

The demonstration of the possibility of growing sterile animals opens up another fertile field for research, namely, the differentiation of the products of bacterial action in the body from those of tissue-metabolism. Investigators have already attempted work in this direction. Thus it may be remembered that Baumann tried to eliminate bacteria and their products from the alimentary tract, by administering calomel to fasting dogs. On the days following the dosage he could find no trace of paired sulphuric acids or of hippuric acids in the urine ; the so-called oxy-acids (hydroparacumaric acid, paroxyphenylacetic acid), however, were present, although in much diminished amounts. Baumann thought, therefore, that the paired sulphuric acids and hippuric acid occurring in the urine of carnivora could be traced directly back to decomposition within the intestine, while the oxy-acids, at least in part, owed their appearance to the metabolic activities of the tissues of the animal itself. As Nuttall and Thierfelder point out, however, there is no good evidence, or even a likelihood, that in Baumann's experiments the intestine was entirely free from living bacteria, notwithstanding the antiseptic action of the calomel, and it is, therefore, quite possible that the small amounts of oxy-acids present in the urine could have had their origin in bacterial decomposition. So far, Nuttall and Thierfelder have been unable to collect from a sterile animal enough urine to permit of such tests, but we are assured that their experiments are by no means as yet completed.

A whole host of allied problems immediately suggest themselves, and it is not improbable that the results of the investigation here reported will mark a new era in the study of the processes of digestion and metabolism. L. F. B.

ECHOES AND NEWS.

ERRATUM. The article on "The Diagnosis and Treatment of Gout," page 64 of THE MEDICAL NEWS, January 18th, should have been credited to Dr. Louis F. Bishop, of New York.

TERRILLON, a distinguished French surgeon, died recently in Paris.

A GRANT of 80,000 francs has been made to the Imperial Institute of Experimental Medicine at St. Petersburg for the purposes of preparing the antitoxin of diphtheria.

DR. E. L. B. GODFREY, of Camden, has been elected Secretary of the State Board of Medical Examiners of New Jersey, in place of Dr. Wm. Perry Newton, who resigned.

NEW ROCHELLE, N. Y., has closed her schools because of the prevalence of diphtheria. The epidemic is reported as quite mild, however, and as nearly as can be ascertained only six deaths from this disease have occurred there within three months.

DR. ABRAHAM WITTON LOZIER died suddenly of heart-disease on the 14th instant. Dr. Lozier had been prominently connected with many educational and charitable institutions during his long and active career in New York City.

AT Montreuil, near Paris, the doctors have refused to give their services to the municipal dispensary, because a woman has been appointed to serve one day in the week. It appears, however, that she is to receive remuneration, while they do not.

THE question of prohibiting the use of matting and other textile fabrics upon the floors of public conveyances, lest they spread disease by collection in them of dried sputum and other morbific material, is now under consideration by the New York Board of Health.

THE Maryland Lunacy Commission in a recent report strongly set forth the baleful influences of hypnotism, especially when practised upon hysterical or nervous individuals, and recommended that public exhibitions of it be suppressed by law.

IT is reported that Emperor William had Prof. Roentgen rush from Wurzburg to Potsdam to give an illustrated lecture to the royal family on his alleged discovery of how to photograph the invisible, and bestowed on him the Order of the Crown, the same second-class decoration that Koch got.

IN the action for $10,000 damages against Dr. Boyden, of Brooklyn, brought by Peter Burggroff for the death of his daughter, which occurred from lockjaw, the alleged result of vaccination, no verdict was reached. The

jury failed to agree, standing 10 to 2 in favor of the defendant.

VIVISECTION IN SWITZERLAND. The inhabitants of Zurich recently rejected, by a vote of 39,476 against 17,297, a proposal for the absolute prohibition of vivisection. On the other hand, a proposal in favor of the protection of animals, with due consideration for the demands of science, was adopted by a vote of 35,191 against 19,551.

AT a meeting of the Medical Faculty of Harvard University on January 4, 1896, a rule was adopted requiring all candidates for admission to this department subsequent to June, 1901, to bring a degree in arts, literature, philosophy, science, or medicine from a recognized college or scientific school. However, the faculty will make exceptions to this rule when individual cases appear to merit such consideration.

NEW YORK CITY at present contains 145 cases of scarlet fever, but the Bureau of Contagious Diseases persists in denying that there is an epidemic. For the past four to six months the public hospitals have found great difficulty in excluding patients with this disease from their wards, where its frequent development is a menace to their usefulness, to say nothing of the aggravating trouble and expense necessary to prevent its spread.

ACTIVE and, it is to be hoped, effective steps are being taken to increase the endowment fund of the Library of the New York Academy of Medicine to $100,000. At the last meeting of the Academy a committee of twenty-five eminent physicians was appointed, who in conjunction with a committee of prominent laymen are to solicit subscriptions. The laymen appointed are Secretary-of-War Lamont, Ex-Governor Flower, Abram S. Hewitt, General E. A. McAlpin, and D. Willis James.

DR. HORATIO C. WOOD was quite seriously injured in Philadelphia on Thursday afternoon (January 16th) in a bicycling accident, and it was only through good fortune that the results of the mishap were not fatal. In attempting to extricate himself from a very uncomfortable position in a crowded thoroughfare, his front wheel caught in the car track and he was thrown over the handle-bar, causing a slight concussion of the brain and two severe scalp-wounds. He was carried to a hospital, but recovered sufficiently in an hour to be taken to his home.

DR. F. W. SHAIN, a prominent physician of Jersey City, fell from his carriage and was picked up dead with a fractured skull on Thursday of last week. While he was driving, Dr. Shain was seen to lean forward as though asleep, and the reins dropped from his hands. The horse walked on, but a moment later the rattle of a Pennsylvania train caused it to shy, and a wheel of the buggy struck one of the pillars of the trestle and Dr. Shain was thrown out. His head struck against the foundation-stone of another pillar and he lay motionless. Dr. Shain had suffered from heart-disease for many years.

FROM Vienna comes the report of some recent scientific advances in photography. It is announced that Prof. Roentgen, of the Wurzburg University, has discovered an electric light which, for purposes of photography, will penetrate wood, flesh, and most other organic substances. Successful impressions were made of the deeper structures of the human body showing the bones and pathological processes, the flesh being invisible. Many other experiments were made, showing that this new light finds in most organic matter no greater obstruction to its passage than glass furnishes to the rays of ordinary light.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

THE Ninetieth Annual Meeting will be held January 28th, 29th, and 30th, in Jermain Hall at Albany, commencing at 9.15 A.M. on the 28th, and ending at 1 P.M. on the 30th. Roswell Park, M.D., President.

FINAL CORRECTED PROGRAMME. Tuesday, January 28, 1896. Morning session. Call to order at 9.15 o'clock. President's Inaugural Address. Appointment of committees. Reports of standing committees and of special committees appointed at last meeting. Annual report of the State Board of Medical Examiners, representing the Medical Society of the State of New York. Executive business.

PAPERS. On Serum-therapy: Dr. E. H. Wilson, Hoagland Laboratory, Brooklyn. Water and its Relations to Disease: Dr. W. P. Mason, Troy (late of the Pasteur Institute, Paris). On Sepsis of the Newborn: Dr. M. A. Crockett, Buffalo. Discussion opened by Drs. Jacobi, of New York, and Jewett, of Brooklyn. The Question of Puerperal Self-infection: Dr. Charles Jewett, Brooklyn. A Medico-legal Note: Dr. A. Walter Suiter, Herkimer. Shall the State Attempt to Control Spread of Tubercular Disease? Dr. J. L. Heffron, Syracuse. Discussion opened by Drs. Jacobi, of New York, and Z. T. Emery, of Brooklyn.

Tuesday Afternoon Session. Call to order at 2.15 P.M. Discussion: On Early and Latent Syphilis in Infants and Young Children; opened by: 1. Dr. George T. Elliott, New York, Diagnosis and Treatment. 2. Dr. Ernest Wende, Buffalo, Pathology. 3. Dr. B. Sachs, New York, Nervous Manifestations. General discussion opened by Dr. L. D. Bulkley, New York. Discussion: Diseases of Intrauterine Life: (*a*) On the Part of the Mother: Dr. E. H. Grandin, New York. (*b*) On the Part of the Child: Dr. P. W. Van Peyma, Buffalo. General discussion opened by Dr. Polk, New York. Address: Medical Education of the Future: Dr. Charles W. Eliot, President of Harvard University. On Sloughing Fibroids Complicating Pregnancy: Dr. M. D. Mann, Buffalo. Discussion opened by Dr. Mundé, New York. The Equilibrium-function of the Ear: Dr. Gaylor P. Clark, Syracuse.

Tuesday Evening Session. Call to order at 7.30 P.M. Scorbutus in Infants: Dr. H. C. MacLean, Brooklyn. Treatment of Malignant Disease in So-called Cancer-institutions: Dr. Nathan Jacobson, Syracuse. Alcoholism and Public Health: Dr. H. R. Hopkins, Buffalo. On the Evolution of Pathology. Illustrated by Lantern-photographs of those who have developed the science,

with illustrations from their works: Dr. J. H. Hunt, Brooklyn.

Wednesday, January 29, 1896. Morning Session at 9 A.M. Abdominal or Vaginal Cœliotomy—Which? Dr. J. W. Whitbeck, Rochester. Vaginal Hysterectomy without Ligations: Dr. W. E. Ford, Utica. Complications in Abdominal Surgery Requiring Intestinal Anastomosis: Dr. Vander Veer, Albany. Some Rare Complications of Appendicitis: Dr. Herman Mynter, Buffalo. The Improved Cæsarean Section: Dr. J. Garrigues, New York. General discussion of above papers by Drs. Etheridge, of Chicago; Mann, of Buffalo; Wylie, Mundé, Boldt, Krug, of New York; and McNaughton of Brooklyn. Treatment of Fractures of the Patella by Continuous Extension, without Confinement in Bed: Dr. J. D. Bryant, New York. Early Diagnosis of Tubercular Kidney: Dr. Willy Meyer, New York. The Symptoms and Diagnosis in the Indigestion of Starches: Dr. Reynold W. Wilcox, New York.

Wednesday Afternoon Session. Call to order at 2.15 P.M. Congenital Dislocation of the Hip, with exhibition of case successfully operated: Dr. T. Halsted Myers, New York. Heteroplasty with Celluloid to Cover Defects in the Skull: Dr. Willy Meyer, New York. Discussion: On the Present Status of the Surgery of the Brain; opened by Dr. E. D. Fisher, New York; Dr. M. A. Starr, New York; Dr. Seneca D. Powell, New York. Surgery of the Skull, Dr. B. Sachs, New York. Surgical Treatment of Epilepsy, Dr. Chas. L. Dana, New York. Craniotomy for Imbecility and Epilepsy, Dr. James W. Putnam, Buffalo; Dr. W. C. Krauss, Buffalo; Dr. George Woolsey, New York. Address: Irritation and Counter-irritation, Prof. Wm. Pepper, Philadelphia. Address: Deficient Excretion from Kidneys not Organically Diseased, in Some of the Disorders Peculiar to Women, Prof. James H. Etheridge, Chicago.

Wednesday Evening Session. In the Senate Chamber, 7.45 P.M. Anniversary Address by the President: On the Study of Pathology by Comparative Methods. To be followed by an informal reception in the State Library and inspection of the new Medical Department of the Library. Annual Dinner at the Kenmore Hotel at 9.30 P.M.

Thursday, January 30, 1896. Morning Session at 9.30 A.M. Reorganization of the Coroner System: Dr. W. G. Macdonald, Albany. Distinctive Fractures of Railroad-surgery: Dr. R. S. Harnden, Waverly. Discussion opened by Dr. C. S. Parkhill, Hornellsville. Diabetes and Acetonuria in Children: Dr. W. S. Cheesman, Auburn. Development of Muscular Atrophy on a Basis of Old Infantile Spinal Paralysis, a Favorable Type: Dr. W. Browning, Brooklyn. To be discussed by Drs. C. F. Barber, Brooklyn, and J. W. Putnam, Buffalo. Value of Animal-extracts in the Treatment of Nervous and Mental Disease: Dr. Floyd S. Crego, Buffalo. On the Surgical Treatment of Retroversions and Retroflexions, with Special Reference to Vaginal Fixation: Dr. H. N. Vineberg, New York. Neuritis Complicating Dislocation of the Shoulder and Elbow: Dr. M. A. Veeder, Lyons. Treatment of Aspiration-pneumonia by Drainage by Inversion: Dr. W. W. Seymour, Troy. Difficult Perineal and Suprapubic Lithotomy: Dr. W. Hailes, Albany. Abscess of the Frontal Sinus: Dr. J. P. Crevering, Auburn. Discussion opened by Dr. T. H. Halsted, Syracuse. Some Notes on Trachoma: Dr. M. L. Foster, New York. Tetanoid Hysteria: Dr. Grace Peckham-Murray, New York. Treatment of Œdema of the Lungs: Dr. Louis Faugères Bishop, New York. Treatment of Sciatica with Nitroglycerin: Dr. W. C. Krauss, Buffalo. Trephining for Injuries and Diseases of the Cranium: Dr. W. W. Seymour, Troy. Second Report on a Case of Functional Albuminuria: Dr. Eli H. Long, Buffalo.

OFFICERS AND COMMITTEES.

President, Roswell Park, Buffalo. Vice President, William Maddren, Brooklyn. Secretary, Frederick C. Curtis, Albany. Treasurer, Charles H. Porter, Albany.

Committee of Arrangements: William J. Nellis, Albany; William Hailes, Albany; William J. Morton, New York.

Committee on By-Laws: H. D. Wey, Elmira; A. R. Simmons, Utica; F. C. Curtis, Albany.

Committee on Hygiene: Lewis Balch, Albany; Lewis S. Pilcher, Brooklyn; D. S. Burr, Binghamton; Z. T. Emery, Brooklyn; E. V. Stoddard, Rochester; O. W. Peck, Oneonta; Lucien Howe, Buffalo.

Committee on Legislation: Seneca D. Powell, New York; Maurice J. Lewi, New York; A. Walter Suiter, Herkimer.

Committee on Medical Ethics: John S. Warren, New York; Charles Jewett, Brooklyn; Eugene Beach, Gloversville.

Committee on Prize Essays: A. Jacobi, New York; Henry Hun, Albany; W. S. Cheesman, Auburn.

Committee on Publication: F. C. Curtis, Albany; William Warren Potter, Buffalo; F. D. Bailey, Brooklyn; C. H. Porter, Albany.

Committee on Credentials: D. S. Burr, Binghamton; T. F. C. Van Allen, Albany; M. L. Bates, Canaan.

OFFICIAL LIST OF THE CHANGES OF THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE 16 DAYS ENDED DECEMBER 31, 1895.

CARTER, H. R., Surgeon. Granted leave of absence for 12 days, December 17, 1895.

WILLIAMS, L. L., Passed Assistant Surgeon. Granted leave of absence for 15 days, December 30, 1895.

MCINTOSH, W. P., Passed Assistant Surgeon. To proceed from Boston, Mass., to Louisville, Ky., and assume command of service, December 28, 1895.

BROWN, B. W., Passed Assistant Surgeon. Granted leave of absence for 9 days, December 17, 1895.

PROCHOZKI, EMIL, Assistant Surgeon. To proceed from Buffalo, N. Y., to Detroit, Mich., for duty, December 28, 1895.

THOMAS, A. R., Assistant Surgeon. To proceed from St. Louis, Mo., to Boston, Mass., for duty, December 28, 1895.

CUMMING, H. S., Assistant Surgeon. Granted leave of absence for 16 days, December 16, 1895. Leave of absence extended 4 days, December 26, 1895.

BOARDS CONVENED.

Board to revive regulations regarding uniforms, Surgeon Fairfax Irwin (Chairman), Passed Assistant Surgeon C. E. Banks, and Passed Assistant Surgeon B. W. Brown (Recorder), December 17, 1895.

Board for the examination of officers for promotion and candidates for admission to the service, to meet in Washington, D. C., February 10, 1896. Surgeon George Purviance (Chairman), Surgeon H. W. Austin, and Surgeon H. R. Carter (Recorder), December 30, 1895.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, FEBRUARY 1, 1896. No. 5.

ORIGINAL ARTICLES.

ON THE VALUE OF THE COMPARATIVE METHOD IN THE STUDY OF PATHOLOGY.[1]

BY ROSWELL PARK, A M., M.D.,
OF BUFFALO, N. Y.;
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BUFFALO.

THE most pleasant, if at the same time the most trying, of the numerous duties which your by-laws entail upon your President is the preparation of an annual address, in which he shall set forth before you the recent progress of our art, or other matters of general professional interest which may prove, if not helpful, at least temporarily entertaining. As I have glanced over the annual addresses of my predecessors, and have noted the wide range of subjects considered by them, and have fully appreciated the value of their work and the eminence of their personalities, I have stood aghast at the task thus set for me. It may happen, however, to any earnest and faithful student of medical science who has made no brilliant discoveries of his own, and who has shown himself nothing more than a zealous traveller along pathways made for him by the feet of others, to view, as it were, regions into which as yet but few paths lead, or which have been untrodden as yet by the footfalls of his fellow-men. Into such regions he may yearn to explore, yet be without the necessary training or preparation. Yet, seeing these, he may sometimes do good by pointing out to others where their own explorations may be required and their time well spent. It must be in some such capacity, if at all, that I must serve you to-night.

I have, consequently, selected for the topic of my address a subject upon which I have at least reflected long and seriously, and have time and again yearned for light that either was not provided or was too obscurely hidden, and in such a way as to be concealed from easy appreciation. My plea, then, with you to-night is for a further extension of methods of comparative study in the investigation of disease and departure from the normal standard. Some such illustration, perhaps, as this may serve better to make known my meaning: There have been various methods devised of studying the languages, living and dead. An extreme in one direction has been to take the advanced grammar, and thus, beginning at the top of the linguistic ladder, gradually work down—a method by which even to-day too many young men waste their time over the study of Latin and Greek, as well as of French and German. The other method, the so-called natural method, has been to begin with the simplest parts of speech, to deduce grammatical rules as the scholar advances, and to carry him along by easy and progressive stages until, at the culmination of his studies, parts of speech and rules for their use come as naturally as do the words which are to be marshalled together into grammatical form. The introduction of methods like this has robbed the study of languages for the children of to-day of most of the terrors which they presented for the children of my generation. The same comparative methods are evident in all the best educational institutions, and are being constantly improved by the best educators. The tendency toward the comparative study of the various branches of science is perhaps happily illustrated in the recent appearance of a text-book on comparative geology (by Keyser). This, perhaps for the first time, does for geology what comparative study has accomplished for botany, zoology, etc. Most of the text-books on geology are confined to the geological phenomena of a single country, the rest of the world being dealt with in a very careless fashion. To be sure, this is in the main due to the fact that the writers worked within altogether too narrow limits, and have little or no personal acquaintance with conditions in countries which to them are foreign. Nevertheless, the key to the great geological problems of our earth is not to be found in any one region, but must be comprehensively viewed and studied. If, now, these methods be important in linguistic study, in geology, and in all the various branches where no one will deny their importance, how much more important are they for us in the study of the medical sciences! If we stop a moment to inquire why it is that this common-sense method of study, as all will allow it, has been so generally disregarded in the medical schools of the world, the answer will probably be found in the utilitarian view, held by many that the time is not sufficient to permit of beginning at the bottom and working up, and that after all it is dis-

[1] Being the President's Annual Address before the Medical Society of the State of New York.

Nulla autem est alli pro certo noscendi via, nisi quam plurimus, et morborum, et dissectionum historias tum aliorum, tum proprias collectus habere, et inter se comparare.—MORGAGNI.

ease in the human race rather than disease in the lower orders with which we are especially to concern ourselves. Potent as is this view in the minds of most, it nevertheless does not permit of full justice to the subject, and should not be permitted to stand in view of the really higher interests of medicine.

While a man may be perfectly competent to reduce a fracture of a fibula, and quickly put the patient upon his feet with a useful limb, who has never heard that the fibula is a disappearing relic, and that in many of the lower animals it is a larger bone, there nevertheless is no reason why in the interests of higher medical education this fact should not be perfectly familiar to him and to all. The man who removes an ovarian tumor successfully and conducts his patient through a speedy convalescence must certainly be considered a competent practitioner of his art, though he may have no comprehension of the peculiar findings within such a tumor, and may be as much at a loss to account for the teeth, the hair, the rudimentary mammary gland, or other structures which he may find there as the original possessor of the growth. Does it follow, however, that he can be considered a really educated man if he prove himself thus ignorant? The surgeon who exposes a dermoid tumor within the cavity of the cranium may have the technical skill by which to remove it and secure a primary wound-healing, and yet be utterly at a loss to account for its presence in that location. Is he to be content with his surgical skill, or are we to expect of him that he shall possess something more than this and be able to tell as much as anyone may know of the secret of such a growth?

I think you will all agree with me that such knowledge is most desirable, and that it really has a large degree of practical or utilitarian value. But how to get it and how to teach it is the great problem before us, and how to disseminate more widely the knowledge now possessed by a few is one of the tasks which the wise men of the present have to set themselves.

First of all, we cannot for one moment afford to lose sight of the fact that our bodies are but aggregations of cells, each of which has its own individuality, even to some extent its own autonomy. Every organized being is then a republic of cells, but it is not yet widely enough appreciated that, as in a republic of citizens, a little disturbance in one region may bring about by most unexpected agencies a disturbance or even a revolution, so in the bodies alike of plants and animals cellular disturbance at one point is sure to affect to greater or less extent the entire economy. In the higher animal and vegetable forms, however, the cellular organization is altogether too complex to permit of a study of the conditions which so disturb inter-relation of parts. If we are, then, to acquire any knowledge or idea as to what goes on within such wonderfully complex organisms as our own, we must begin by the study of those which are vastly simpler. In this connection I want to lay before you as a model in my estimation of what such study should mean the *Researches on Inflammations*, by that indefatigable Russian biologist, Metschnikoff, who has for some years been so prominent a figure in the Pasteur Institute in Paris. If there be any one phenomenon concerning which we need more positive and exact notions than another, it seems to be this very one of inflammation. The changes attending it in complex organisms are so complicated and give rise to such wide diversity of disturbance, tissue-alterations, and results, that we cannot afford to disregard one thing concerning it which may be gained from any source. Although this has been conceded for centuries, and although John Hunter appreciated the fact, and like many others worked long and arduously at the solution of some of its attendant problems, it was Metschnikoff who, more than any other living man, in my estimation, has made the process clear, simply because he began to study it in the lowest forms of living beings. To anyone who will read his fascinating work, the advantages of this method will be made so clearly apparent that he will wish that every pathological laboratory had its corps of Metschnikoffs in order to pursue work along the same general lines and by the same methods. But for our purposes and in various ways I would go even further than this. I would say that the beginning of all pathological processes, as of all physiological, should be studied in the vegetable kingdom first, where may be found the parallels of all those changes which go to constitute disease, even of complex type, in the human race. The elements of plant-physiology may be reasonably mastered within a comparatively short time without going too deeply into the principles of ontogeny and phylogeny; but if the circulation, for instance, is to be studied, it certainly can be best studied under conditions where it is most simple, and I would vastly prefer to see the student trained to know how the sap makes its way through the length and breadth of a tree before he begins to think of how the blood circulates through his own frame. It is better that he should work up to a knowledge of the circulation if his medical education is to be complete, than work down to the simple after having begun with the complex. After he has mastered the normal circulation in plants, he will then be in a position the better to appreciate what takes place when a plant is wounded, and he will learn to distinguish between the true hemorrhage of vegetable organisms and a true exudation, and the differences between mere outpour of vegetable juices due to

solution of continuity, and the pathological secretions which takes place when the parts have been irritated by parasites, exposure to injuries by vicissitudes of weather, or have had the character of their secretions materially, sometimes almost totally, altered by variation of surroundings, changes in soil, etc.

How much better, then, to begin studying the activities of cells in the lowest and most immature organisms first. If the study be begun in this way, it will be seen that the formative activity of cells dominates over their secretive activity, and it will be found, for instance, that those cells which have passed out of the gland as waste products may remain and proliferate more or less independently. This, by the way, may be a factor in explaining the genesis of cancer; *e. g.*, in the breast. It will be seen, too, that the behavior of cells as well often as of organs (composed of them) depends in large degree upon the quantity and quality of nutritive material which is at disposal. Thus, among the bees it depends upon the nutrition supplied to the female larva whether it shall remain a neuter or become a sexually perfect female.

There is one law, however, of cellular physiology which is apparently never violated, and that is, that a derivative of one germ-layer never by any chance develops a structure originally derived from another. Consequently after differentiation of the blastodermic membranes no wholly indefinite cells are formed. Those cells which are thereafter formed can develop only certain tissues. But all these cells are directed by some unseen force, even when they appear uncontrolled, and in a suitable environment will always tend to arrange themselves into the form of the organism from which they originated. Thus, a small detached bit of hydra soon moulds itself into the complete shape of the parent organism. The property of selective assimilation seems to be possessed by cells in common, and those of a given part appear to have the power of moulding adjacent material into cells after their own kind. This is shown by the fact that a tail is reproduced where there was a tail, and a leg, and only a leg, where there was a leg. These processes have been likened to those by which a crystal reproduces its lost apex when placed in a solution of identical material. The lower the animal or vegetable form the more complete is the power to reproduce the lost parts; the higher we ascend the scale the more limited does this become, until in man the ability to reproduce lost parts is almost completely gone, and when noted at all is seen only during the beginnings of life or its early stages, at a time when there is still more or less embryonic tissue which can functionate. Thus, during the early periods of embryonic life there may be more or less complete reproduction of fingers after injury, though nothing of the kind occurs in adults. There are cases on record of reproduction of supernumerary digits after amputation, which seems the more remarkable because the normal digits have no such power of regrowth, the nearest approach being the occasional appearance of imperfect nails on finger-stumps after amputation. Simpson several times noted that arms amputated *in utero* by bands grew again to a certain extent, while in one case the extremity was divided into three minute nodules, on two of which small points of nails could be detected. This is probably as far as attempts of this kind have ever been observed in our own species. In the same way in plants, adventitious buds, like adventitious fingers in the fœtus, differ from the normal only in respect to position. Such buds originate in the same way and have been found upon almost every part of plants. They sometimes develop in extraordinary numbers upon the stem and branches of trees owing to some interference with the vegetation of the normal buds. More easy adaptation of part to circumstance is, however, seen in the vegetable than in the animal kingdom. Du Hamel planted a willow with its branches in the ground and its roots in the air and saw the roots become covered with buds, while the budding branches produced roots. Adventitious buds may also be found on the petiole, lamina, and other parts of the leaf. Thus the bud, like the ovum, is to be regarded as an individual vital centre. Parthenogenesis, which never occurs in the animal kingdom, may be frequently seen in the vegetable, and buds apparently may arise where undifferentiated cells are present.

In either kingdom, however, so soon as cells begin to specialize they lose the primary general function or power of reproducing the entire organism, apparently because all of the original protoplasm has been specialized and used up. In the higher organisms certain cells never attain high development, but remain always in a lowly organized condition and serve either as germs for reproducing the entire individual or for forming and maintaining various tissues and organs, remaining, as it were, in reserve. Such cells are found in all growing organs and tissues, and, according to Williams, are the only real cancer- or tumor-germs. Most of the specialized cells of an organism produce only those which are incapable of acting as germs for an entire individual; *e. g.*, epithelium always produces epithelium.

Since much of what I have to say to-night pertains to the genesis of tumors, it may be worth while to reiterate Williams's views to the effect that every phenomenon of neoplastic growth has its counterpart in the normal processes of evolution, and that the better we understand the latter the better we shall appreciate the former. On the one

hand, there is continuous perfecting of bodily structure by differentiation; on the other, continuous transition from lower to higher types of development. Each individual reproduces in its own life the most important morphological changes through which its long line of ancestors has passed. In every act of reproduction a minute quantity of protoplasm is transferred from the producing to the produced offspring, and along with it the molecular condition peculiar to the parents; and upon this heredity depends. The persistence of impressions, or what has been called unconscious memory in protoplasm, is the property upon which, in ultimate analysis, the phenomena of heredity will be found to depend. Organisms which have undergone impressions under new conditions tend to return to the original structure or habits when restored to original surroundings. When we seek for the influence most potent to produce variation in protoplasm, we must agree with Darwin, who says: "Of all the causes which induce variability, excess of food, whether or not changed in nature, is probably the most powerful." Viewed in this light, the sudden development of a neoplasm in an otherwise healthy organism is the outcome of gradual and continuous changes in the evolution of the cells of the affected part, owing to minute and as yet unrecognizable changes in the nutrition of the cells. Regard for a moment the effect of too much or too little nourishment. Young trees, for instance, often remain sterile because of too rich soil and too much excess of fluids; while too warm a temperature hastens the second sprouting, the necessary juices are kept away from the first, and fruit blossoms may be prevented from developing. Among the little insects known as plant-lice agamic multiplication continues throughout the summer if only external conditions—*i. e.*, weather and supply of nutrition—are favorable; but when the weather becomes cold and the supply of sap in the plant fails, fertilization of ova is again necessary.

But study vegetable pathology for a few moments, regarding plants as if they were animals and likening the sap to the circulating blood. Carrying out this analogy, the vegetable pathologists describe what they call ischæmia and even necrosis in plants, and show how these may occur from injury to the roots, from interference with circulation caused by grafting, from abusing the tree, from early frost, improper soil, etc. They show also the alteration in natural fluids in the presence of disease; and it is of some interest to know that the secretions of parts involved in necrotic or so-called cancerous changes contain gallic and humic acids. Furthermore, studying the effect of alterations in light and air, they describe conditions of plant life analogous to chlorosis and icterus, alleging perverted nutrition, usually in the direction of too much and too rich food with too abundant moisture as the causes of these conditions. They also describe what they call dry gangrene, while in the presence of stasis with decomposition of the fluids which should be circulating there is sufficient irritation with perversion of nutrition to influence cell-growth into the development of so-called cancer in trees.

In my estimation there is as much hope of getting light upon the vexed question of origin of tumors by the study of influences operating to produce them in plants and trees as from any other source. The influence of certain fungi in producing sclerotic changes in vegetable tissues is also very much in accord with what we know to result in animal tissues from the presence of parasites. There is, for instance, the peculiar fungus known as the peziza, which produces most extensive sclerotic changes, both internally and near the surface. The great beauty of studying disease in vegetable life is the abundance of material and the absence of sentiment concerning its utilization. A great deal of vegetable pathology is yet to be learned by the inoculation-method, since there is just as much possibility of deliberately infecting trees by artificial inoculation with various parasites, to them pathogenic, as there is in our pathological laboratories of infecting animals.

And here, by the way, the expert agriculturist or the student of scientific agriculture, horticulture, etc., in our agricultural colleges is a person whom the veterinarian and the human pathologist would do well to cultivate, since to such a one are known many facts of to him great practical importance, which yet have a significance reaching far beyond his environment and embodying general principles with which we ought to be equally familiar, although, sad to say, we seldom are. I often consider it a great pity that there are not societies where men in these various walks of life may get together and disseminate more widely a knowledge which physicians as such rarely, if ever, possess, but which could be by such communications made of great value.

For example, the reaction of vegetable tissue after wounds is even to physicians most instructive. If after bruising of a plant, for instance, the bruised portion be left *in situ* it decomposes easily, while the wound itself heals with difficulty or even not at all, and necrosis of surrounding tissue often follows. Is not this the exact counterpart of what one might say of wounds of the animal body? It is of passing interest even to remember that hailstones may produce injuries, contusions, etc., which shall materially affect the nutrition of a plant or tree, and that contused wounds made in this way may be followed by more or less disastrous results. There is also a difference between what we may call the bleeding of a tree and pathological secretion after certain injuries. The latter originates in and near the injured part;

the chemical nature of the secretion is altered, and a variety of materials, to us most useful, are in this way produced, although the causes have in but rare instances been studied out. For example, the various resinous materials, and such substances as tragacanth, manna, and other gums, are all pathological secretions produced in consequence of more or less specific irritations. Then, again, open wounds in trees give peculiar opportunity for microbic infection or that by other parasitic fungi, which, as a rule, cause necrosis of the plant- or wood-tissue. Such infections, however, in trees rarely spread widely, and the resulting necrosis is for the most part local. Only those products of decomposition which are soluble are diffused into surrounding tissues, where their influence may be injurious. Hemorrhage, so-called, in plants is the result of a fresh wound, the peculiar juices, sap, etc., exuding, possibly to an extent so serious as to lead to the death of the plant. The most damaging exudate, however, is that of gum from trees after their foilage is out; the reason for which is that the exudate exerts such pressure that there is stasis, and even coagulation of fluids between the cortex and the woody part of the tree, by which circulation is impeded. Again, it often happens, as the result of frostbite during foliage, that the cortex (bark) may rupture and permit escape of this coagulated secretion from the disturbed part. All of which only makes things worse, since there is now thrown out a still more irritating secretion (often spoken of by agriculturists as chilblains), which not seldom forms an open cancer upon the tree. In a minor way, pathological flow of gum is also produced by the stings of beetles, and of many other insects which lay their eggs in the cortex, the lesion then being strikingly analogous to that produced beneath an animal's skin by the sting of certain insects, etc.

Yet different is the peculiar yellowish, sticky, sweetish-tasting substance, of unpleasant odor, often seen upon the upper surface of the leaves and stems of many plants, where it may gather within a few hours. This is commonly spoken of as "honey-dew" (melligo). It is an abnormal secretion of certain plants whose juices are rich in sugar. It is most commonly found in the spring after sudden changes of temperature, escaping from the cells, through the pores, upon the surface of the plant, where, combining with the moisture of the atmosphere, especially during the cool of the night, it is precipitated upon the surface, thus closing the pores from which it has escaped, and interfering with their function as well as with the growth of the plant. This may be washed off during a severe rain; but if not removed by natural processes, is liable to ferment, it being quickly attacked by minute fungi. The benefit to infected trees and plants of severe rain and wind, which are thus destructive agents of these fungi and permit the re-establishment of normal vegetable function, is then most easily appreciated.

In plants and animals alike, the process of repair and the neoplastic tendency are closely allied, differing only in degree. The new growth of repair serves to replace that which has been lost; while that of neoplasms is indefinite and knows no bounds, the subordination of local processes to tissue-necessities and to specific hereditary tendencies having been lost.

The *formation of tumors in trees* seems to me a subject of very great interest. All the woody tumors have been grouped in a general way under the term "xylomata," while among some of the botanists they are indiscriminately called cancer. In the majority of cases the so-called cancers of plants occur around the sites of previous injury, where the natural process of healing has been interfered with, and where the cambium produces an abnormal amount of parenchyma instead of healthy wood. Lesions of vegetable tissue produced by frostbites are particularly liable to be followed by these xylomatous formations. They may also be produced by the stings of many of the small parasitic animals, like plant-lice. The pyrenomycetes are known to be the cause of some of the xylomata. In the populus tremulus, for example, the stems and branches often show tumors of varying, even of large, size, the hypertrophy commencing in the cortex, involving all or only part of a limb, being followed by swelling of the wood proper, and later perhaps by destruction of the cortex by frostbite, with exposure of the wood beneath, necrosis ensuing. The importance of the lesions produced by exposure to cold is not generally realized. It is, moreover, of peculiar interest that trees inoculated with cancerous sprouts or grafts become themselves cancerous (Lucas). Lorauer has described two forms of so-called cancer in the apple-tree, both of which seem to result from frostbite—one a rose-like growth with a necrotic centre surrounded by terrace-like edges, enlarging yearly; the other, a closed form of growth appearing upon branches, attaining a size three or four times that of the plant, with a funnel-like depression, the edges of the original lesion rolling in toward each other instead of diverging as in the previous case. Physicians are made familiar with a very limited number of these xylomata when they study the materia medica of the astringents, and are told about the origin of gallic acid. The student is informed that the nutgall is the result of irritation produced by an insect, and that perhaps at least one hundred species of gall are known upon the oak; but here his acquaintance with the xylomata ceases, and he is taught no far-reaching lesson from this fact in vegetable pathology.

Perhaps the most instructive animal-parasites of

trees and plants to watch and study are the so-called plant-lice, since they pass their whole lives upon plants and draw from them their nourishment. These little insects fasten upon the plant by suction, puncturing the part and producing an irritative action which is followed by a variety of lesions, from hypertrophy of irritated tissue to speedy necrosis. The hypertrophies may have the character of true galls. One form of plant-mildew indeed is produced by these same little animals, being in effect the empty sloughs which they leave behind and which remain as a white mass upon the green surface. These same plant-lice are the active agents in the production of certain tumors often spoken of as cancer. But it is especially the so-called blood-lice, which live in young plants and thrive best in fresh wounds, which lead to most marked neoplasms. The blood-louse is an almost motionless parasite, which attacks young plants upon wound-edges, where it finds the tissues thin enough to have ready access to the plant-juices. When this parasite has fastened, the cambium becomes more active and hypertrophied, while the plant-cells, being now exposed, absorb moisture and swell even to the point of bursting. By this means long, elliptical clefts are formed, and these often become the site of so-called cancers. It will thus be seen that nearly all, if not all, of the so-called xylomata are really of parasitic origin. It will not do, however, to argue too loosely from this fact that the same thing is true in the animal-world. We at least have not yet sufficient evidence to make so positive a statement.

The xylomata have been divided by Williams into three main groups:

A. Discontinuous or circumscribed growths, to which the vague name of "knaurs" should be restricted. This includes nodules so often met in the bark of common trees. These are usually rounded swellings in the deeper part of the bark, varying in size from a pin-head to a cocoanut, usually encapsulated, often with fibro-vascular pedicles connecting broader portions with the woody tissues of the trunk or stem. These on section consist of dense wood showing all the structural elements of the tissue from which they spring, only atypically arranged. Most of these tumors arise from disorderly growth of adventitious or dormant buds, which may remain in quiescent state for years and then develop renewed activity. These tumors may even be utilized for purposes of propagation, as in the case of buds of some species of apples, which produce both roots and leaves in abundance.

B. Continuous tumors, corresponding to exostoses in animals, presenting as woody outgrowths of the trunk or plant. They may attain great size, weighing fifty pounds or more. They seem to arise by excessive local cell-proliferation of the cambium.

C. Totally new growths, presenting a surface thickly studded with shoots and stunted branches. This is a combination, in fact, of exostosis with diffuse bud-formation—that is, of the preceding forms.

For the cellular pathologist, then, a tumor in an animal or upon a tree is practically the same, it making no difference even whether it occur upon the bark, upon the leaf, or anywhere, provided only that a previous pathological lesion has occurred. The nut-gall which arises in consequence of the puncture of an insect, the tuberous swellings which mark the spots on trees where boughs have been cut off, and the wall-like elevation which forms around the border of the wounded surface produced by cutting down a tree, and which ultimately covers in that surface, all of these depend upon proliferation of cells just as abundant, just as rapid, as that which we perceive in the growing tumor in the human body. The process in plants conforms practically to that in animals, both being of the same general type.

Malignancy of tumor-formation is largely a process of cell-degeneration and incompetence. When in animals it begins in mesoblastic connective tissue, the more imperfect the cell-development the more of the round-celled type it assumes in consequence. Hence the malignancy of sarcoma is to be judged of quite accurately by the roundness and incompleteness of its component cells. In benign tumors the reproduction of cells is more orderly, but is not in harmony with the demands of the rest of the system. The simplest of all the body-tissues is its fatty tissue, and fatty tumors are the most frequent of all benign growths; while true gland-tissue, which is most difficult to irritate, furnishes the smallest number. True cancer has been described most attractively as a "parody upon the gland-tissue;" and it certainly is a hideous travesty of its kind. It occurs most often in tissue which has outlived its usefulness, like the mamma, the uterus, etc.; and it is in such tissue, for the most part, that true carcinoma, or the so-called "rebellion of the cells," occurs (Hutchinson), while epitheliomata occur also in worn-out tissue, usually under the stimulus of some irritation. Epitheliomata are rare among the lower animals as compared with man, and when met with at all occur most often in the domesticated animals and those in confinement. Sarcomata are common in all classes of animals, from the fish upward; but even these are more common among those ordinarily domesticated. (Possibly this is only an apparent prevalence rather than a real, because of much greater familiarity with animals in domestication.) Carnivorous animals are more prone to malignant disease than are the herbivorous, while the reverse is true with regard to liability to tuberculosis. Cartilaginous tumors, particularly in the breast, are much more common in animals than in man. The quadrumana, however, manifest but

little disposition either to neoplasms or to tuberculosis.

In cancer atavism, or reversion to an earlier type, may be traced back to the hydroid stage, where simple fission is the prevailing method of multiplication; in consequence of which we have a longer-lived and more aggressive cell-growth, which we call malignant. If a mesoblastic cell be the ringleader instead of an epiblastic, we then have sarcoma with its less brilliant but more stable cellular achievements (Hutchinson).

These neoplasms are not peculiar, as will be seen and as has been seen, to man, nor even to animals, although it must be stated that epithelial neoplasms are of rare occurrence in the lower animals as compared with mankind, and that they are apparently more common among the domesticated than among wild animals. On the other hand, sarcomata have been met with in nearly all classes of animals, from fish upward, although these also occur most often among the domesticated. Dogs, horses, asses, and pigs are particularly liable to sarcoma of the testicle. Horses, especially those of light color, are most prone to melanotic sarcoma of the anal region. Horses are also quite often victims of psammoma in the brain. According to Rayer, carnivorous animals are more prone to malignant disease than herbivorous. The benign tumors, like fibroma, enchondroma, and osteoma, are almost as widely diffused as sarcoma. Fatty tumors are frequently seen in domesticated animals. Mammary fibro-adenoma among dogs and cats is fairly common, and chondroma of the mammary gland is much more frequent among animals than among man. Cystic ovaries are also common in the domestic animals.

(To be concluded.)

POST-MORTEM CÆSAREAN SECTION, WITH DELIVERY OF A LIVING CHILD.

By EDWARD P. DAVIS, A.M., M.D.,
of Philadelphia;
Professor of Obstetrics in the Philadelphia Polyclinic; Clinical Professor of Obstetrics in the Jefferson Medical College; Attending Obstetrician to the Philadelphia Hospital, etc.

Sudden death of the mother during labor, if the child is living, makes it obligatory upon the attending physician to endeavor to rescue the infant. The success of such an attempt will depend, first, upon the nature of the cause which destroys the life of the mother; second, upon the time chosen for the delivery; and, third, upon the method employed.

Two causes of maternal death are especially fatal to the fœtus. One is traumatism, resulting in severe hemorrhage to the mother, and the other is an infection, producing high fever and profound intoxication. Sudden death in labor from heart-lesions or from mechanical injury, without great hemorrhage, gives conditions most favorable for the survival of the child.

The time for accomplishing delivery in these cases is necessarily brief. A recent case is reported by Hoffman[1] in which in an eclamptic patient he describes the delivery of a living child by abdominal and uterine incision ten minutes after the mother had ceased to breathe. It may scarcely be supposed that a longer delay than this could be borne by the fœtus. Where high temperature is present, the time must be necessarily briefer in which successful delivery may be accomplished.

The method of performing rapid delivery in these cases has been variously chosen by different operators; while abdominal and uterine incision is undoubtedly quickest, some prefer forcible dilatation of the uterus, and forceps or version. The practical choice of a method must depend upon the condition of the birth-canal, and also the circumstances and situation of the patient. Where abundant assistance is at hand, the patient can quickly be put in suitable posture for the forceps or version. Where, however, but little help can be obtained, and the patient cannot be placed in proper position readily, it is often more easy to perform abdominal incision.

The survival of children so delivered will depend upon the vigor of the child, and also upon the nature of the cause which destroyed the mother's life. The acute infections are especially fatal to infants, not only from the action of poisonous germs conveyed from mother to child, but also by reason of the high temperature which is often present in these cases.

A recent case may serve to illustrate the foregoing remarks:

The patient, Mrs. L., aged twenty-six years, a primipara, had been in good health during her pregnancy. She was of good constitution, and had always enjoyed excellent health. A few days before her death she had summoned her physician with the complaint of headache, restlessness, and nervous discomfort. He prescribed a sedative for her which somewhat relieved her symptoms. Shortly afterward, while sitting with her family, she was suddenly seized with convulsions, and soon became unconscious. Her physician was at once summoned, and applied the usual methods of treatment for subduing the eclamptic seizures. These were, however, unsuccessful, and the patient rapidly passed into a comatose condition with extensive œdema of the lungs. I saw her in consultation about six hours after the first attack. She was then in deep coma, with a high temperature and labored breathing. Vaginal examination disclosed the membranes un-

[1] Centralblatt für Gynäkologie, 1895, No. 50.

ruptured, the cervix obliterated, and the os about three-fourths dilated. It seemed to me possible to rupture the membranes, complete dilatation with the hand, and apply forceps, as the vertex was presenting. While hastily preparing the forceps, the patient was seized with a convulsion, at the close of which she expired. I hurriedly asked whether the family desired that an effort be made to save the child, and was informed that such was their wish. As the patient was a large, stout woman, and her bed so placed that she could not be put into position for the use of forceps without considerable difficulty, the quickest method of delivery seemed abdominal incision. Accordingly, while one of the physicians held a light, the abdomen and uterus were rapidly opened, and a male child, weighing 7 pounds and 12 ounces, was extracted. In the hurry of the moment, the patient's temperature had not been taken, but her body felt so hot to the hand that her temperature must have been above 104°. The child was asphyxiated, but speedily revived and breathed naturally. As the child would be without skilled care if left at home, he was immediately warmly wrapped, placed between warmed pillows, and taken to the Jefferson Maternity, where he was placed in an incubator. He was nursed by a healthy young woman whose child was but a few days old, and was given the faithful care of trained nurses. It was observed that the child perspired very freely upon entrance to the Maternity, and that the secretion of urine at first was excessive. The child nursed naturally, its bowels were soon emptied, and its appetite was excellent. It gradually developed, however, symptoms of toxæmia, similar to those of an eclamptic patient. Its urine contained a great excess of uric acid, its skin became dry, and its bowel-movements were dark in color. The child was treated as would be a woman suffering from toxæmia. It derived the greatest comfort from a warm pack. Its intestines were irrigated, and simple diuretics were administered freely. The toxæmic condition considerably improved, and the child continued to nurse regularly. It never had convulsions, and slept when its excretory organs were freely stimulated. At the end of two weeks, however, it developed a purpuric condition of the skin and mucous membrane of the intestine, and died two weeks after delivery from inanition.

This case illustrates very perfectly the pathology of eclampsia, and the toxæmic condition transmitted to the child which proved so fatal to the mother. It was most interesting to observe that all of the child's nervous symptoms, restlessness, and suffering were directly relieved by that form of treatment which increased its excretions. In view of the fact that the child survived two weeks, that it nursed, and was relieved for a considerable time of threatening symptoms, the attempt to save its life seems to have been justifiable. As a post-mortem examination could not be obtained upon mother or child, the exact pathology of both cases could not be ascertained. Every symptom, however, pointed in mother and child to a profound toxæmia as the cause of the fatal issue.

This case illustrates most pointedly the imperative necessity of watching carefully the excretory processes of the pregnant patient. It is not sufficient to ascertain simply the presence or absence of albumin in the urine, but the physician must know that the skin, kidneys, liver, intestines, and lungs of the mother are performing the double duty which the presence of the fœtus entails. When this is carefully watched, sudden and profound intoxications like that described will rarely happen. An experienced observer will detect the effects of toxæmia upon the nervous system, and by suitable diet and prompt stimulation of the organs of excretion will, in the great majority of cases, succeed in averting the danger to mother and child. In the presence of profound toxæmia with eclampsia there is but a short time in which any form of treatment is of the slightest avail. The fatal line is passed so rapidly that, unless the physician is forearmed and forewarned, he may find himself in the presence of an unpreventable catastrophe.

RESULTS OF TREATMENT OF RHEUMATIC FIBROUS ANKYLOSIS BY BRISEMENT FORCÉ.[1]

BY W. R. TOWNSEND, A.M., M.D.,
OF NEW YORK.

IN Foster's *Encyclopædic Medical Dictionary* ankylosis is defined as "any morbid condition of a joint in which its mobility is abolished or decidedly impaired." True ankylosis is bony in nature, while the false is that due to any other cause. There are several varieties of the false, the muscular being due to contraction of the muscles around the articulation, thus preventing free motion; the extracapsular, in which causes outside the joint, such as destruction of tissue and cicatrices, limit the motion, and the fibrous, caused by the development of adventitious fibrous tissue in or around the joint, the more serious cases being those in which it is within the joint.

A clear conception of these different varieties is absolutely necessary for many reasons. By ascertaining, if possible, whether the ankylosis is extra- or intra-articular, we may learn something of the history of the morbid process that produced it, and also be guided as to treatment and in making a prognosis.

In the first place, it is clearly understood that it is essential to determine whether, in a given case

[1] Read before the Orthopædic Section of the New York Academy of Medicine, January 17, 1896.

of ankylosis, the true or false condition exists, and that few will commit the error of the surgeon referred to by Mr. Brodhurst, of treating by extension for fourteen years a case of bony ankylosis in the hope of securing motion, or of the surgeon, Louvrier, who, elated with his great success in treating ankylosis, moved to a larger city and then failed completely, because he could not distinguish between the false and the true. In many cases an anæsthetic is necessary, and it is then seldom difficult to distinguish between the two.

A review of the literature of the subject shows that most of the authorities speak of fibrous ankylosis as synonymous with the false, and use the terms indiscriminately. To the student who desires information as to how to treat a given case, the knowledge to be obtained is most unsatisfactory. Some of the well-known text-books on surgery do not mention the subject at all; others dismiss it with a very few lines, and those that give the subject a chapter, no matter how brief, are not many in number.

Young[1] says "That treatment should not be undertaken until the original articular disease has disappeared or has been overcome by appropriate treatment, since too early manipulation may hasten what the surgeon is trying to overcome. The reduction in mild cases of false ankylosis can be accomplished by gradual manual and elastic traction. In more severe cases, forcible reduction (brisement forcé) may be performed with or without anæsthesia . . . the prognosis is generally good under modern surgical methods."

Bradford and Lovett[2] speak of ankylosis under the head of Etiology of Chronic Joint-disease, but say nothing of the treatment of the fibrous variety due to rheumatism.

Sayre[3] devotes two chapters to the subject and gives full and complete directions as to how brisement forcé should be used, and states clearly what steps should be taken in the after-treatment of the case. He publishes a number of most gratifying results, but says nothing of his failures, and makes no distinction between fibrous and other forms of false ankylosis. His work, however, is the best on the subject.

Ashhurst[4] says that we can improve position by brisement forcé, and that in those cases where we desire to produce mobility passive motion must be employed on the third day, the inference being that the desired result is secured.

The American Text-book of Surgery[5] says: "In the majority of cases a fibrous ankylosis will require for its removal either a forcible rapid breaking up of the adhesions and straightening of the limb, or a slowly effected correction of the deformity by continuous or intermittent traction, etc., but that both at the elbow and at the knee (after fracture of the patella) a resulting fibrous ankylosis, if forcibly broken up, will commonly be quickly reproduced, but with active use of the joint will generally spontaneously disappear in the course of a few months, or at most in a year or two."

Mansell Moullin[1] speaks of brisement forcé, and compares it with the partial and slow method, and gives most excellent advice as to the future management of the case, but is not at all clear as to the results produced.

Schreiber[2] has a most excellent article on ankylosis, but does not state positively what result may be expected after brisement forcé.

When we consider the monographs on the subject of the treatment of fibrous ankylosis, we find that brisement forcé has been recommended by Brodhurst, Bauer, Ollier, Palasciano, Velpeau, Bonnet, Buhring, Dieffenbach, Langenbeck, and many others.

Brodhurst[3] says that he had performed 267 operations for false ankylosis without a bad result, but does not give the details of the cases. He quotes Bauer as saying that he had seen 600 cases of contraction and ankylosis, and thus had most ample opportunity for most thorough clinical observation; and that all were agreed on the superiority of forcible rupture of adhesions as compared with gradual extension, and that the former opponents have been silenced by the overwhelming results which have been produced.

Brodhurst advises gradual extension, with or without tenotomy, or immediate flexion of the limb, with or without tenotomy, and subsequent gradual extension.

I have quoted thus at length to show that with but few exceptions brisement forcé is most highly commended, and yet are the results satisfactory in fibrous ankylosis due to rheumatism is a question that may well be asked. Some recent writers have stated that the adhesions may be reproduced, but not one has come out clearly to show the limits of the procedure. It certainly has its limits, and from a study of the cases here appended it would appear that, except to correct deformity, it is not productive of good results in cases of polyarticular rheumatism. Whether electrolysis will benefit such cases is an interesting subject, and has been carefully studied by Guyer,[4] to whose article the readers are referred,

as this paper is simply a report of the results of brisement forcé in the treatment of fibrous ankylosis due to rheumatism in the cases the author has personal knowledge of.

Some may argue that most of them were not suitable for the operation, and that a failure might have been expected. My only reply is that practically every text-book on surgery recommends the procedure and says nothing of its limitations or failures, and it seemed justifiable in every instance. In the eleven cases reported, one complete success was achieved, in a case where only the shoulder was involved; one partial success, but it really can hardly be said to be due to brisement forcé, as it was only attempted once, and the subsequent treatment should really be credited with the result. The nine failures were all in cases of multiple fibrous ankylosis, rheumatic in character. Where a slight amount of motion exists at the time of bending the joint there is perhaps a slight hope in some cases of benefit, and in those cases where the adhesions snap, as in a fracture, the prognosis seems better than where they tear. It should be used to correct deformity unless the correction renders the patient's condition really worse, as in Cases V. and VI., where a flexion-deformity of the hip was corrected, and now with the hips fully extended the patient cannot sit down. Of course, it was hoped to have motion, or the limbs would have been left in the flexed position. Where we bend the hips we should, therefore, be careful to place them in such a position that if the ankylosis remains a sitting posture can be assumed; in other words, leave a moderate amount of flexion-deformity. In every case we must be sure that no active disease exists at the time of the operation, and it would seem better if after a failure to secure motion we did not repeat the procedure too soon, but rather rely on massage, electricity, douches, and such measures. The mistake may have been made in some of these cases of moving the joint too freely, but the cases that were only partially moved do not seem to have done any better than those that were moved through the full range of normal joint-motion. Many of the reported cures in literature were undoubtedly in individuals in whom no fibrous adhesions had taken place within the joint, but were cases of extra-articular adhesions or of muscular contractions. In others, however, there is no reason to doubt that true fibrous intra-articular adhesions existed, but in most of these successes only one joint was involved and polyarticular rheumatism is generally more severe in character than the monoarticular variety.

The accidents that may be caused by the use of too much force or by force improperly applied may be serious in character, but in only one of the cases reported do we believe a fracture occurred, and in but one instance was the integument torn. Cases I. and II. were personal, the others were seen at the Hospital for Ruptured and Crippled or in the private practice of Dr. Gibney, through whose courtesy I am enabled to report them.

CASE I.—Female, single, aged twenty-one years. Admitted to Polyclinic Hospital January 26, 1895. Family history negative. Without known cause developed rheumatism in both knees and left elbow eight months previous; was treated in best possible manner in another hospital, both by internal and external medication, and had made a good recovery except that both knees were ankylosed in a straight position. Left knee could be moved voluntarily over an arc of about 10°. No motion in the right. Patellæ movable.

January 29. Under ether-anæsthesia left knee forcibly stretched to full limit of flexion and back to the straight position; much force was required, and tissues within the joint seemed to tear rather than break or snap. The patient was put back to bed, limb firmly bandaged, and cold applications made to the knee. A posterior splint applied to the leg and thigh. Patient suffered much pain and had to be given opiates for three days.

February 6. Any attempts at motion cause great pain. Is again given ether and same procedure repeated. This time the adhesions gave way more easily.

13th. Patient had less pain after the last operation, but cannot stand the pain of attempts to move the knee. There has been no swelling and very little extra heat in the joint as the result of the manipulation under ether.

20th. Under ether the left knee is moved and the right knee moved from the straight line to a fully flexed position, and then after being firmly bandaged is put up in a plaster-of-Paris splint midway between full flexion and extension.

23d. Pain is so great that the plaster has to be removed and limbs put up in a straight position. Massage is applied to the left knee, but is very painful.

No further efforts were made in this case, and when seen two months later both knees were perfectly stiff and fully extended.

CASE II.—Female, married, aged twenty-six years. Family history negative. Three years previous had an attack of inflammatory rheumatism in the left knee and the right wrist. The wrist had completely recovered. The knee was firmly ankylosed within about 10° of full extension; the patella immovable. The joint slightly smaller than that of opposite side. Patient was nervous and much worried at her inability to bend the knee, and as there were no contraindications, under full ether-anæsthesia, on March 14, 1895, the adhesions were broken up and fully extended first and then fully flexed. The foot was elevated and an ice-bag applied to the knee. She suffered much pain after the operation, but at the end of one week could move the knee voluntarily over an arc of 10°.

March 28. Under ether the limb again moved through the full range of extension and flexion and bandage applied and cold applications. Patient had less pain, and in a week was walking around

and moving a limb over an arc of about 15°. She kept trying to move the limb herself, and on several occasions I moved it for her, but could not increase the range of motion, and invariably caused great pain. The case was not seen after July 1st, but at that date there was no further gain in motion.

CASE III.—Female, single, admitted to Hospital for Ruptured and Crippled, November 1, 1892. Family history negative. Exact date of beginning of trouble unknown. On admission she is found to be much deformed. Has a bad lateral curvature; lies on the left side, with the left thigh adducted 45°, flexed to 80°, and rotated inward, thus completely closing the vaginal outlet. There is no motion in the hip; the knee is held flexed at 90°, but has a fair range of motion. The right thigh is abducted about 45° and extended to 120°. She has numerous cicatrices on various parts of the body, due to bedsores. The right foot is in equinus. December 1st, under ether, the left thigh is partially extended and abducted. Much force is required, and a tear in the soft parts results in the region of the left labium and marked venous hemorrhage follows. Shortly after this she developed a severe albuminuria, and no further efforts were made to correct the deformities.

CASE IV.—Female, aged fourteen years, single, admitted to the Hospital for Ruptured and Crippled, May 17, 1894. Family history negative. In 1885 her ankles became swollen, and at the end of four or five months it was noticed that both feet were drawn up, and that the joints of fingers of both hands were also affected. Massage, baths, and internal medication were resorted to and kept up for three years, but with no improvement. She is now unable to walk or stand. Lies on her back, the forearms flexed on the arms, the hips flexed on the pelvis, the knees on the hips. The right shoulder has fair range of motion, the elbow has flexion to 120°, extension to 80°; the wrist has slight motion. The left upper extremity is the same as the right. The first to fourth lumbar vertebræ project markedly and give the appearance of a Pott's disease. The hips are fixed at 130° of extension and permit of 10° of passive motion. The knees are firmly fixed at 90°, and the tibiæ subluxated. Patella fixed. The motion of ankle-joints is limited.

May 20. Has a Billroth splint applied to each knee, and by August 25th the right has been extended to 140°, the left to 135°.

26th. Under ether the knees are forcibly straightened to 180°. On October 3d daily massage is begun and on December 1st passive motion. She can now walk a little. The fibrous adhesions about the finger-joints are less marked.

March 13. Under nitrous oxide anæsthesia the knees are repeatedly and rapidly flexed and extended and then strapped with rubber adhesive plaster. This operation is repeated on October 16th and 23d, and from that time limbs immersed daily in hot water and rubbed. On January 1st, 15th, 29th, February 12th, 26th, and March 12th and 26th nitrous oxide is given and knees moved freely. On June 25th she is discharged; the shoulders and hips are stiff; the knees are movable, the right between 110° and 170°, the left between 100° and 170°; and patient can walk a little better.

CASE V.—Female, aged twenty years, admitted to the Hospital for Ruptured and Crippled, June 10, 1893. Five years prior to this date she had an attack of rheumatism, beginning in the knees and gradually extending to all the other joints of the body. The left shoulder, elbow, and wrist are stiff; the joints of the fingers badly distorted and enlarged; the right hip is extended to 140°, the left to 130°. Slight motion in the right, none in the left. The knees are held at 60° of flexion. Patellæ immovable.

July 14, 1893. Under gas the knees are stretched and plaster of Paris applied.

28th. Left knee fully extended under gas-anæsthesia.

September 1. The left hip fully extended under gas; it comes down with a sharp noise, and it is suspected that a fracture of the surgical neck of the femur has been made, but this cannot be positively made out. Plaster-of-Paris spica applied.

15th. Under gas the right knee forcibly stretched.

29th. Under gas the right knee again stretched.

October 23. Develops pleurisy on left side.

November 26. Massage and galvanism applied daily to the knees.

January 18, 1894. Limbs are thoroughly bandaged, and patient given Fowler's solution in increasing doses.

February 1. A slough appears on posterior aspect of the left leg, due to pressure.

May 10. Rubbed daily with salicylic acid in lanolin-ointment. From that time on various drugs were tried, including salol and protonuclein, but at the present date, January 17, 1896, her knees and hips are both ankylosed in the straight position, and only improvement noted in her condition is that she has a slightly better use of the finger-joints and of the left shoulder, parts which have been under no treatment.

CASE VI.—Female, aged nine years, admitted to Hospital for Ruptured and Crippled, September 28, 1884. In 1884 had inflammatory rheumatism. Both knees, hips, wrists, and finger-joints affected. She has motion over a small arc in all of them. The right hip can be extended to 120°, flexed to 90°. The left hip can be extended to 120°, flexed to 110°. Weights are applied to the limbs, and iodide of potash given internally. She had several attacks of acute rheumatism, and was treated by internal medication, was sent to Saratoga for three months in 1891, and had massage faithfully applied between 1887 and 1892, when, on April 26th, she was given ether, the adductions of the thigh divided, and the fascia lata of both sides and limbs were then put up in a straight position in a plaster-of-Paris spica. Since then she has had massage, and has been gradually gaining a little more motion each year, until to-day, January 19, 1896, she can walk quite well, but has a shuffling gait, and can only go slowly. The right hip can be extended to 180°, flexed to 140°. The left hip can be extended to 180°, flexed to 140°. The knees are straight.

Right has motion between 180° and 150°, and the left between 180° and 140°. She thus has to sit with knees projecting somewhat. The joints of the upper extremity have also improved, and she can dress herself and sew quite nicely.

CASE VI.—Male, aged seventeen years, admitted to Polyclinic Hospital, October 27, 1893. At the age of seven had a fall, injuring the right thigh, and soon after developed rheumatism in that hip. He was confined to bed for a week, and after getting up noticed that the limb was shorter and joint stiff. Two years later had trouble in his left hip. At the age of thirteen had rheumatism in both ankles, and later in both knees. Six months ago had similar attack in the temporo-maxillary articulations. His parents are healthy, but a maternal aunt and two maternal uncles have had rheumatism. He walks on crutches, and the joints of the upper extremity are all normal except the left elbow, which is stiff. Both hips are ankylosed at 110° of extension in moderate adduction, and rotation inward. No motion in the left, very slight amount in the right.

The right knee held firmly at 150°, but can be moved with some force to 90°; fluid in both joints. No grating, patellæ free. Ankles enlarged, motion through half normal arc.

31st. Under ether-anæsthesia (primary) the hips are moved over a small arc, firmly bandaged, and a weight and pulley applied.

November 6. Under ether-anæsthesia (primary) hips further moved.

January 26, 1894. Left knee straightened and hip moved; much force used.

May 9. Knees and hips straightened; has much pain.

July 11. Is having daily massage and hot fomentations. The left hip is in good position. No motion at hip, knee, or ankle. Right hip in moderate abduction, extended to 155°. No motion at any joints of this limb.

A note from the patient in 1895 states that he has no motion in joints of the lower extremity, and as limbs are straight cannot sit down.

CASE VII.—Female, aged twenty-two years, single. Seen November 23, 1889. Family history negative. In July last had an attack of inflammatory rheumatism involving the right elbow and left wrist. Was confined to bed for six weeks. Her elbow is firmly ankylosed at 160° of extension. No swelling. Her wrist held fixed at 150° extension. Attempts to move the wrist cause pain.

November 25. Under chloroform-anæsthesia the wrist is straightened and hyperextended.

December 13. Wrist is straight and has about 5° of motion. Active movements advised and a stimulating liniment.

February 6, 1890. Is given an apparatus to move the elbow.

May 22. Elbow broken up under ether-anæsthesia; joint snapped, no fracture produced, moved freely.

June 10, 14, 19, and July 16. Ether-anæsthesia, and elbow moved freely.

October 30. No motion in elbow. Patient seen three years later. No motion in elbow or wrist.

CASE VIII.—Female, aged twenty-five years, single, admitted to Polyclinic Hospital, December 18, 1887. Seven years ago had inflammatory rheumatism in left wrist, then one joint after another became stiff and to day both shoulders have very limited amount of motion. Elbows have limited range of motion. The wrists have 10° of motion and firmly held, the right in 150° of extension, the left at 170°. The finger-joints are stiff. The right hip firmly ankylosed at 135° extension, with no adduction; the left fixed at same angle with slight adduction. The knees are fixed at 135°, right with tibia rotated outward, the left with tibia normal. The ankles stiff, feet in moderate equinus, toes hyperextended. Is ordered iodide of potash in increasing doses.

October 24. Under ether-anæsthesia all attempts to move right lower extremity failed. Left hip moved in abduction, flexion, and extension over a small arc. Limb firmly bandaged and ice-cap applied to knee.

31st. Left hip brought straight and knee and ankle. Foot put up in good position in plaster of Paris.

November 11. Under ether right knee, hip, and foot straightened. Tendo Achillis divided.

14th. Under ether motion obtained in both hips, firm flannel bandage applied to limb, and over this plaster of Paris.

January 27. Both hips and knees firmly ankylosed. Under ether the adhesions are broken up; patellæ immovable, left tendo Achillis divided.

March 5. Under ether the hips, knees, ankles, and left elbow broken up.

April 17, 1892. Is walking on crutches. All the joints of the lower extremity firmly ankylosed. No motion whatever. Upper extremity same as when first seen. No improvement noted.

CASE IX.—Male, aged thirty-one years. Seen October 1, 1886. Was in good health until September, 1885, when he developed rheumatism in right foot, hand, and wrist, and in left shoulder, knee, and ankle.

October 2. Under ether-anæsthesia the right wrist and ankle broken up, then strapped with adhesive plaster.

November 24. Brisement forcé again done under anæsthesia.

December 21. No motion in joints operated on.

CASE X.—Male, aged twenty-seven years. Seen in 1884. Had been subjected to brisement forcé on right knee at different times by the late Dr. Sands in 1882, and by the late Dr. Roberts in 1884. Knee now perfectly stiff.

CASE XI.—Male, aged forty-four years. Seen in 1885. In May of that year had rheumatism in left shoulder, which was left perfectly stiff.

September 23. Under ether-anæsthesia the shoulder moved freely in every direction. After this hot douches and the Paquelin are applied.

October 23. Under ether the adhesions are again broken up.

November 2. Cannot move the shoulder. Is ordered massage.

February, 1886. Much improved.

June 15, 1887. Result perfect. Can move one shoulder as well as the other.

NEW YORK CITY, 28 WEST FIFTY-NINTH STREET,

ORIGINAL ADDRESS.

A REMARKABLE CASE OF GASTRITIS GRAVIS.

BY TH. ROSENHEIM, M.D.,
OF BERLIN, GERMANY.

Translated from Transactions of the Berlin Medical Society,

BY A. L. BENEDICT, A.M., M.D.,
LECTURER ON DIGESTIVE DISEASES, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO.

AUGUSTA W., aged fifty-eight years, of healthy family, has had typhus (typhoid, probably) twice and pneumonia three times. She has borne four children, which died early of some brain-trouble and quinsy. For twenty years she has suffered with headache, leading to rheumatic pains, but the stomach has always been healthy. Ten weeks ago, in March, 1893, headache began to be attended with loss of appetite, and later vomiting set in. After two weeks she was so exhausted as to be unable to leave her bed. The pains in the head were localized mostly in the temples and over the brow. They were accompanied by darting pains in the muscles of all the extremities. Occasionally enuresis occurred. Then speech became rather slow and difficult, and for the last four weeks she has suffered with breathlessness and palpitation of the heart. There has been progressive emaciation since the beginning of the trouble. Present condition, May 20th, on admission to the hospital—pale, exhausted, emaciated, of marked bony development, a few ecchymotic spots on the chest; in the most dependent portions of the chest, catarrhal râles. Respiration regular, 24 to the minute; heart normal; pulse 100; knee-jerk present; fibrillary twitchings and slight tremor of the tongue. Blood-examination without significance. In the abdomen a hard resistance is felt about the pylorus, quite tender on pressure. Stomach displaced and dilated; serious motor disturbance. No albumin in urine. Fundus of eyes normal.

May 25. Has vomited repeatedly in the last few days. Constipated. Improvement from administration of bits of ice and sherry. Occasional rise of temperature to 38.6.° Passages firm, scanty, without pathological significance.

June 3. In spite of careful diet and lavage, vomiting has returned. The stomach-contents are odorless, containing no sarcinæ; free hydrochloric acid never present, but the contents are acid and uniformly give the reaction of lactic acid after the usual test-breakfast. Slight febrile movement, with acceleration of pulse, from time to time. Urine free from albumin. Progressive emaciation.

10th. Further examination of the digestive apparatus shows that there is no obstacle in the œsophagus. Stomach dilated; the resistance originally felt has become a tumor about the size of a walnut—that is, hard and slightly painful on pressure, very movable and doubtless connected with the pylorus. Passages from bowels scanty. Stomach-contents lack hydrochloric acid; Uffelmann-test present.

21st. Stomach has been washed out pretty regularly. A subjective improvement has occurred, but the appetite remains poor in spite of medicines, and the weakness increases. Free hydrochloric acid always absent; Uffelmann's test present. Very little nourishment for weeks. The tumor is plainly palpable, as before. Traces of albumin in the urine, without casts. No œdema. In the last fourteen days no febrile movement.

After marked failure of strength the patient died June 26th, the diagnosis having been made of carcinoma of the pylorus.

At the autopsy there were observed great emaciation, bronchitis, slight thickening of the heart-valves, atrophy of the liver, spleen, and kidneys. Intestine and brain normal. No trace of carcinoma of the stomach, and the stomach was given to me for more thorough examination. I found it strongly dilated, the greater oblique diameter being 28 cm., the distance of pylorus from cardia 20 cm. Mucous membrane pale gray. Pylorus penetrable by the finger; walls thicker than normal, 7–9 mm. The thickness was due to an increase in the muscular coat, which in some places measured 6 mm., the normal being 4 mm. Macrosopically, the mucous membrane at the pylorus showed no marked change, but that of the fundus, and especially toward the cardia, was too smooth and thin.

Microscopically there was found:

1. At the pylorus, hypertrophy of the muscularis, with spots of infiltration; vascular walls thickened in the submucosa, muscularis mucosæ partly penetrated by infiltration; the true mucosa shows interstitial growth, to which a compression of the glands is partially due. Normal tubules opening freely on the surface are sparse. Although the nuclei for the most part stain well, almost none of the secretory epithelium shows sharp contours. Some of the tubes are filled with hyaline masses which stain grayish-blue with hæmatoxylin and contain some particles that stain deep blue, the latter being, in some places, arranged along the walls of the tubules.

2. The wall of the fundus is not thickened. The muscularis is beset with infiltrations here and there. In the submucosa are a few hemorrhages. The glands of the submucosa are compressed by the strongly hypertrophied interstitial tissue; only the smaller proportion are atrophied. The secretory epithelium is normal only in places. Its place is taken in part by a pretty diffusely staining mass of nuclei.

3. In the cardiac portion the wall of the organ is thinnest, and the mucosa especially abnormally thin. Glands discharging freely on the surface are absent; the remains of the glands, in spite of vertical sections through the mucous membrane, are cut obliquely and lie deeply and crowded together. The epithelium of the glands is changed in the same way as in the fundus.

There is no macroscopical abnormality of the intestine. Its secretory and resorbtive function was scarcely altered according to clinical observations. The microscopical examination of the tissues supported this view. At the autopsy there was shown to be carcinoma of the pylorus, which was of normal calibre. Except bronchitis and marked emaciation, there was nothing but atrophy of the great abdominal glands. The more careful examination of the stomach showed only a considerable benign hypertrophy of the pylorus muscle and a severe chronic gastritis tending to atrophy, which

could be considered as of pretty high grade in the fundus near the cardia.

Can the findings of the autopsy in the stomach explain the clinical picture and death? I believe we may answer this question in the affirmative, although total atrophy was not present. We know that gastric atrophy is not a rare occurrence. Quite apart from atrophic changes which accompany carcinoma, this form of gastritis can be established as an independent disease. As such, it is rather frequent in elderly persons, particularly old women (Ewald); but it is occasionally noticed in quite young persons, as in the following case that I have had under observation for years:

Fred. B., thirteen years old, presented himself in 1889, complaining of gastric oppression and pain. Vomiting had been frequent of late and the pains were cramp-like. The appetite and the condition of the bowels were normal. He was a small, well-built, well-nourished boy, with a healthy complexion. Almost all of the back teeth and several of the front ones were lacking. There was a grayish-white coat on the tongue. Gastric area tender on pressure. About 30 c.c. of the test-breakfast were removed and appeared as if they had been chewed and spit into the glass directly. Reaction neutral, no peptone. The scanty filtrate, after the addition of hydrochloric acid, showed a delay in the solution of fibrin up to four hours. No marked motor trouble. The patient was frequently examined in the next eight months, the results not being especially significant. Codeine, pancreatin, and lavage ameliorated the symptoms, but there has been no change in the secretory activity of the stomach, as shown by an examination that I made in July, 1894. The dental defect was undoubtedly the cause of the severe gastritis passing into glandular atrophy.

That atrophy of the mucous membrane of the stomach is a grave affection, sufficient alone to cause death, is proved by the researches of Fenwick, Nothnagel, Quincke, Ewald, Rosenheim, and others. In some of the observations contributed up to date the affection has presented the picture of a progressive anæmia. (Nothnagel, Quincke, Henry and Osler, Rosenheim.) At times symptoms have appeared indicating degenerative processes in the cord—paresis, muscular spasm, atrophy, loss of patellar reflex, etc. Eisenlohr found in his case of atrophy of the gastric and intestinal mucous membrane that ran its course with the above-mentioned symptoms, the signs of grave anæmia, degeneration of the lateral and posterior columns. With our patient, Augusta W., the anæmia was only of such character as would be expected in any cachexia. Nervous symptoms, except headache, enuresis, palpitation of the heart, etc., which could be explained by the weakness, were absent. In the foreground were the loss of appetite and vomiting, without especial complaint of pain, and these symptoms could be explained solely by the gastritis, leading to atrophy. The gastric symptoms of this malady are very diverse. Pains, especially cramps, are present in part of the cases, vomiting is quite frequently lacking; the most frequent symptom is complete loss of appetite. Vomiting, in our patient, may well be ascribed to the dilatation that developed in the dislocated organ. Lavage might mitigate this symptom temporarily, but the motor function did not improve under this treatment, so that stagnation and consecutive vomiting always returned. Even if the ingestion of nourishment was limited essentially by the anorexia, only a fraction of what little was taken was utilized. Granting that assimilation remained normal—the feces were always formed and presented no abnormality—the small quantity of nourishment that reached the secretion could not possibly maintain the balance of nutrition. The rapid emaciation shows how seriously the economy was injured. It is clear that, in spite of loss of appetite, such a failure of strength would not have taken place if all that reached the stomach was really utilized. The critical point of the situation lies, therefore, in the disturbance of the motor function of the stomach. In none of the cases thus far published is the weight of this factor so plainly shown as in ours. We know that when the gastric secretion fails a compensatory activity may devolve upon the intestine, and, as long as the latter organ remains healthy, the general nutrition is good and patients may survive for years without losing the appearance of health. But the situation changes as soon as the food, which is not altered in nor absorbed from the stomach, remains there as the result of damage to the motor function. Herein is the importance of a dislocation of the stomach, which is so common in women, and which doubtless favors the development of atony and dilatation. As the motor weakness makes itself felt the organism seeks to compensate for the disturbance by hypertrophy of the musculature and certainly succeeds for a time; but the hypertrophied muscle, after years it may be, becomes insufficient, and then begin the symptoms of disease. The weakness of the muscular apparatus is not explicable by the pathological changes found therein. The slight interstitial hyperplasia indicates only that mild inflammatory processes have occurred, but we cannot see how they have influenced the motor activity of the organ. At last, for every hypertrophied muscle, whether of the heart or stomach, comes a time of failure, and this condition is capable of improvement only temporarily, if at all. The rapid course in our case is most remarkable, the duration from the first marked symptom till death being scarcely six months. Nothing, however, would be more erroneous than to suppose that the whole pathological process in the stomach occupied only so short a time. That atrophic processes in the gastric mucosa may develop with extraordinary rapidity, is shown by similar changes that we note as accompaniments of carcinoma; but in the vast majority of idiopathic atrophies the development and course are extremely chronic. The inflammatory process here occupied a long time, and the first complaints coincided with the failure of motor power. The considerable febrile disturbance, for which a cause could not be found, does not contradict the diagnosis of gastric cancer, since it is not rarely observed in that condition.

Among the signs of disease which were afforded by the stomach, the tumor remains to be explained. It was felt by all the examiners—its position, hardness, respiratory movements, and movability under the hand—all these signs, taken in connection with the other symptoms, left no doubt that we had to deal with a malignant neoplasm at the pylorus. Even a gradual enlargement was noticed, the easier and more exact palpability of the swelling, on account of the progressive emacia-

tion, being deceptive. All points of diagnosis always led us to the opinion of cancer. That form of disease known as cirrhosis, as well as the anomaly described as hypertrophic stenosis, was pretty unanimously excluded, on the ground that the course of the disease lacked chronicity. There was nothing to indicate a foreign body in the stomach; a peritoneal exudate was excluded by the extraordinary mobility and the slight tenderness of the tumor. There was nothing to justify the belief that there was an infiltration of the gastric wall at the base of an ulcer.

There is no doubt that hypertrophy of the pyloric muscle may simulate a neoplasm. Leube expressly states that swelling due to hypertrophy cannot be distinguished from a smooth and small pyloric carcinoma; that consecutive dilatation of the stomach and chronic gastritis are common to both. He bases his differential diagnosis on the origin of the condition and the exclusion of a cancerous cachexia, but our patient left us in the lurch so far as these points of differentiation were concerned.

Finally, when we consider the constant lack of free hydrochloric acid and the persistence of lactic acid in the gastric contents, the diagnosis of cancer seemed to be well founded. According to J. Boas, the distinction of such processes as we have here considered, from carcinoma, must depend on the positive occurrence of the ferric-chloride test, which is pathognomonic of cancer, since "lactic-acid production is a specific sign of gastric carcinoma." Boas has been the first to show the relation between gastric cancer and the lactic-acid reaction, but he goes too far in estimating the value of his discovery. It is doubtless true that, in the great majority of cases in which a distinct ferric-chloride test is obtained, there is gastric carcinoma. Exceptionally, Uffelmann's test can occur in other pathological conditions, as our experience teaches. If the reaction occurs in the filtrate of the gastric juice, removed at the height of digestion, after a test-breakfast, and occurs sharply—that is, shows a yellowish-green tint—it is significant as indicating positively that the lactic acid amounts to at least 5 : 1000, and such a finding is always pathological. On the other hand, the positive occurrence of the reaction in the ethereal extract is without diagnostic significance, since the slight traces of lactic acid that are necessary to render this possible are often found normally. Especially is this true when the test is carried on according to Fleischer's method, shaking the ether with the reagent and letting them settle. Even such traces as may be present in white bread or in Knorr's oatmeal are recognized by Fleischer's method. Boas has, therefore, further directed to give the oatmeal-gruel after washing out the stomach, and to apply the test for lactic acid according to his aldehyde method. This method was published after the death of our patient, and there were at that time no other methods to render possible a decisive test. From my control-experiments I can say positively that Boas's reaction, quite apart from its complexity, never succeeds where a marked Uffelmann-test does not occur. We have seen that the treatment by lavage was not sufficient to correct the motor weakness of the stomach. According to my experience, in the treatment of atony and dilatation of the stomach, the employment of electricity can scarcely supply the needed contractile energy. Nevertheless, in individual cases, the attempt ought to be made with intraventricular galvanism or faradism; but even when the weak organ shows itself incapable of forcing along the ingesta our armamentarium is not exhausted, and we can still appeal to surgery. Gastroenterostomy, performed by a skilful hand, is a safe operation, unless the loss of strength has proceeded too far. Of our last nine gastric patients on whom Dr. Hahn has operated, not one has succumbed, and the requisite functional compensation has been obtained. The stagnation has disappeared, and even the exhausted muscular wall is still strong enough to drive the ingesta through the hole in the deepest portion of the fundus into the intestine. Donin has lately again called attention to the favorable functional results of this operation in the case of ulcerative contraction of the pylorus, and I can cite similar life-saving results from my own experience. In my opinion, an anatomical obstacle is not necessary to justify operation. The salient point is the motor failure entirely apart from its origin. If it cannot be restored by medical treatment in a reasonable time, the case belongs to the surgical clinic. Exploratory cœliotomy is quite insignificant, and, after local inspection, a decision can be made as to the best plan to pursue. Considering the chances that an operation would have given in our case, we must admit that a gastro-enterostomy, undertaken at the right time, would probably have saved the patient's life. In a case of Westphalin's, similar to ours—that is, without constriction of the pylorus—gastro-enterostomy was done. The patient died on the fourth day, but the interference was made too late. Besides, there was well-advanced phthisis. The bad result in such cases is often due to the misapprehension that operation is a last resort, so that surgical interference is too long delayed.

CLINICAL MEMORANDUM.

APPENDICEAL ABSCESS OPENED THROUGH THE VAGINA.

By P. GUNTERMANN, M.D.,
of Louisville, Ky.

On September 4, 1895, I was called to see a young woman, aged thirty years, the mother of two children. Both labors were normal, both children living and healthy. The patient stated that she had never been ill in her life. She was small and wiry-looking, and gave evidence of perfect health.

The history is that on the second day of September she was taken with acute pain in the right iliac region. She is a woman that bears pain remarkably well. She did not at first think that the attack amounted to very much, but at night she was compelled to go to bed. She took some of the ordinary household remedies—paregoric, whiskey, etc.—which gave no relief. Some time during that night a neighboring physician was called, who prescribed, and the next day saw the patient twice. The pain at no time abated.

I was asked to see the case on September 4th, the third day of her illness, and found her suffering with intense iliac pain, vomiting, and purging. Her temperature at that time was 105° F., pulse 130, with a cold, clammy perspiration. There was some resistance in the right iliac region, much more than was present in the left.

After due consideration, I concluded that it was a case of appendicitis, and one which demanded prompt surgical interference. I sent for my friend, Dr. W. H. Wathen. We went together to see the patient in the morning about six o'clock, and found her then in profound shock. As soon as possible we secured the ambulance and brought her to the Infirmary. Under the influence of hypodermatic injections of morphine, etc., she rallied. She was, of course, not in condition to be operated upon that day, and, strange to say, in the evening her temperature went down, the pulse became less frequent, and the next morning she was feverless, and had nearly a normal pulse. Pain in the iliac region had very much subsided, but she had constant crawling pains throughout the abdomen. She had more or less diarrhœa all the time, three or four passages a day, preceded by some pain and followed by excessive pain. She went on in this way without fever—temperature 98½° to 99° F., pulse 70 to 80—for ten days.

On September 15th I saw her about noon, and noticed a strangely changed appearance in her features as soon as I entered the room. Her expression bore evidences of intense suffering; her extremities were cold; a cold, clammy perspiration was present over the surface of her body; pulse 130; temperature 101° F. I went at once for Dr. Wathen, as the case presented a very serious aspect. Previous vaginal examinations had been made, revealing no trouble about the vagina, womb, or pelvis; but upon this occasion, when Dr. Wathen introduced his finger into the vagina, an immense tumor was discovered, and it was then decided to operate upon her either that night or the following morning. Operation was performed the next morning by the vagina. There was a very large abscess found after making an incision behind the uterus, which discharged about a quart of fluid—so-called laudable pus. It was not very offensive at first, but directly it became fecal in odor, and some fecal matter was also discharged. This abscess was thoroughly evacuated and irrigated with bichloride solution; the opening was made very large, a tube was introduced, gauze inserted, and the patient put to bed. The operation was borne very well, and after the patient was put in bed the pulse came down to 90, temperature to about normal the same day. The following two days considerable fecal matter was discharged through the drainage-tube. On the third day Dr. Wathen removed part of the dressing, no fecal matter being found; the drainage-tube was caught in the adhesions or new plastic formations that filled the cavity, and two days afterward the balance of the gauze was removed, there being no discharge, but the drainage-tube was left *in situ*, where it still remains, the discharge through it, however, being insignificant, amounting, perhaps, to a tablespoonful in the twenty-four hours.

I diagnosed the case as one of appendicitis from the beginning, and subsequent results have proved that it was appendicitis with the formation of a retroperitoneal abscess which had to be opened by the vagina. This feature is something new to me, and I believe it is also to Dr. Wathen. There can be no doubt that it was a case of appendicitis. The operation was performed less than two weeks ago, and the patient has done remarkably well. She has been sitting up for two days, and says she feels almost well enough to be taken home.

MEDICAL PROGRESS.

Remarkable Persistence of Diphtheria-bacilli in Nasal Mucus.—At a recent meeting of the Société Médicale des Hôpitaux, LEGENDRE and POCHON (*Progrès Médical*, 1895, No. 52, p. 459) reported the case of a child that had been under observation for fifteen months, during which it was affected three times with diphtheria (once angina, once stomatitis and rhinitis, once rhinitis and angina). Bacteriological examination made methodically on thirteen different occasions demonstrated the presence of diphtheria-bacilli, sometimes virulent, sometimes not, varying in form and size, and sometimes alone and sometimes associated with staphylococci. The organisms would disappear upon antiseptic irrigation, but would reappear when this was withheld. The case illustrates the condition of latent microbism.

The Influence of Nuclein-containing Food upon Uric-acid Formation.—As the result of a clinico-physiologic investigation, UMBER (*Zeitsch. für klinische Medicin*, Band xxix. Heft 1 and 2, p. 174) has determined that the daily ingestion of 500 grammes of thymus is attended with a distinct increase in the elimination of uric acid, as compared with the daily use of 500 grammes of muscular tissue. The daily ingestion of 300 grammes of thymus, however, increases but slightly such elimination. The daily ingestion of 500 grammes of liver induces varying degrees of increase in the excretion of uric acid, while the ingestion of the kidneys and the brain of the calf brings about changes in the elimination of uric acid comparable with those following the use of muscular tissue. When there is a preponderance of milk in the diet the excretion of uric acid is less than upon meat-diet. The amount of xanthin-bases excreted in health varies widely. It is increased by the ingestion of alkalies and also by the use of a milk-diet.

The Coagulation of the Blood and the Salts of Lime.—As the result of an experimental investigation, ARTHUS (*Archives de Physiologie*, 1896, No. 1, p. 47) has determined that all of the salts (oxalates, fluorides, soaps) that possess the property of precipitating the salts of calcium from their solutions possess, in quantities in which they are not decalcifying, also the property of rendering the blood not coagulable spontaneously. When to blood-plasma containing oxalates in the proportion of 1 to 1000 are added several parts of magnesium chloride (which does not cause any precipitation of the dissolved oxalates) the coagulation of the plasma may be effected by very small quantities of calcic salts—quantities insufficient to precipitate the dissolved oxalates. It thus appears that the coagulation of the fibrin may take place in the presence of a large excess of oxalates, provided that by a suitable method a small quantity of the salts of calcium is maintained in solution and free. When the excess of oxalates is removed by dialysis from the plasma coagulation may not take place, although a sufficient amount of sodium chloride is present to insure the precipitation of the fibrin. These facts go to show that blood containing oxalates in solution is not coagulable spontaneously because it is decalcified and not because it contains oxalates. It thus results that the presence of the salts of calcium in solution in the blood is a necessary condition of coagulation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, FEBRUARY 1, 1896.

CORPORAL PUNISHMENT IN INSTITUTIONS.

MR. DUDLEY WARNER, a strong advocate of corporal punishment in reformatories, characterizes those who oppose cruel disciplinary methods in public institutions as suffering from "*moral mushiness.*" The report of cruelties practised upon the inmates of the "Westchester Temporary Home for Destitute Children," at White Plains, N. Y., by the State Board of Charities would seem to prove that there are some people in Westchester of Mr. Warner's way of thinking. Here is a charity having a large Board of Managers, who are the most respectable ladies in that county, in which the method of punishing children who have attempted to escape is to chain the legs together at the ankles and compel them to wear the chain day and night for months. In one case the child wore a chain, weighing three pounds, seven months continuously. The chain was fastened on each ankle by padlocks and with such slight protection of the skin that a callous ring had formed around the ankles. The State Board of Charities, we believe, expressed the better sentiment of the people of that county in the declaration:

"That whatever may be said in favor of or against corporal punishment by whipping of children in families or in common schools, its tolerence in corporate and private institutions, without its natural restraints of parental instincts in the family, and of public criticism in the common school, is a tolerance that cannot be divorced from an evitable tendency to abuse; and further, that once admitted as an exceptional or extraordinary remedy, its use inevitably extends, until it becomes the chief reliance for enforcing discipline, and that familiarity with this form of correction leads to cruelty, brutality, and inhumanity, and is pernicious in its influence on both officers and inmates, and in the end detrimental to discipline."

It is gratifying to notice, also, that the Board not only condemned these cruel methods in general, but instructed its Secretary

"to forthwith notify the managers of the Westchester Temporary Home for Children, in writing, that the use of chains upon the children in its custody for punishment or restraint must at once be stopped and that corporal punishment upon such children must be abandoned, and that upon failure to comply with this instruction this Board will issue its mandate under the Constitution and the statutes, and proceed to enforce the same."

PREFERENCE OF THE DIPHTHERIA-BACILLUS FOR THE TONSIL.

IT has long been a somewhat puzzling problem to clinicians just why the tonsil is almost universally the point of attack in diphtheria. Its peculiarly exposed position at the junction of the food- and air-passages, and liability to infection from both sources, are possibly responsible for part of this, but certainly not for such a strikingly "bad eminence" as it possesses in this respect. For it obviously is not half as liable to air infection as the turbinated bodies, or to food infection as the mouth or the stomach, being merely brushed by the food in its passage from one to the other, and yet it is at least five times as frequently the site of attack as either. Another theory is that being a rudimentary organ, or lymphoid aggregation around the mouth at the second bronchial cleft, it is a *locus minoræ resistentiæ*, and hence specially vulnerable; but any such "historic" weakness as this would certainly be more than overbalanced by the fact that the mass has been secondarily developed into a leucocyte-breeder and sanitary-police-barracks for the entire upper alimentary canal, so that for a germ to choose this as a breeding place would be like a burglar attempting to rob a police-station, if this be the only factor.

An interesting light has been thrown upon the problem by the methods adopted in cultivating the Klebs-Loeffler bacillus for the manufacture of Behr-

ing's antitoxin. After starting a culture upon its nutrient medium, it was found that the production of the toxin went on quite rapidly at first, but in a very short time began to diminish and finally almost ceased. If, however, the air in the flask above the culture was now renewed, the production began again at once, so that by constantly changing the air the production continued unchecked, while by passing a rapid, constant current of air through the flask it was formed three or four times as rapidly as before. An essential part of the perfected routine now is the maintenance of a rapid current of air (sterilized) through the flasks containing the culture-media by means of a hydrostatic vacuum-apparatus, by which the requisite degree of virulence in the culture can be developed in about one-fourth of the time required under the old "dead-air" method. Evidently the bacillus flourishes best not only in the presence of oxygen, but in a current of air. And where in the entire alimentary canal can this requisite be met except upon the back part of the inner surface of the tonsil? Which is precisely the point of attack in 80 per cent. of our cases. It seems to be pretty clearly established that diphtheria almost invariably enters the system through the alimentary canal, either in the food or drink, or by labial contact, and the comparative immunity of the mucosa of both mouth and stomach from attack has been a matter of surprise, for which, however, the absence of an air-current in these situations gives, at least, a plausible explanation. The mouth is, of course, frequently attacked, and the stomach in rare instances, but both almost always secondarily, after the germ has gained a vigorous foothold upon the ventilated surface of the tonsil. This demand of the germ also helps to explain its marked tendency to extend along the air-passages rather than the alimentary tube, and also the fact that its most vigorous and virulent growth occurs at the point where the air-current is most rapid, the interior of the larynx, the trachea, and especially upon the vocal cords. The extreme virulence and high death-rate from systemic poisoning and heart-failure of diphtheria of the nasal passages are also more easily understood. May not the special liability of the nerves of the palate-muscles in general, and azygos uvulæ in particular, to peripheral neuritis and paralysis after diphtheria, be partially due to their nearness on both aspects to surfaces swept by a current of air and hence peculiarly suited to the development of a virulent form of the toxins?

Fortunately, however, the tonsil is, to use a Hibernicism, not only the most vulnerable, but one of the best protected places in the body. For every dart nature seems to have a shield. And in this case the shield consists of the swarms of leucocytes poured forth by the gland. They cannot defeat the enemy in a fair fight upon a field of his own choosing, for they are sappers and miners rather than riflemen, but they bravely bar his way into the heart of the country by a solid rampart of rank upon rank of their dead bodies. This is the famous and much-maligned "membrane," which happily in a large majority of cases is successful in mechanically cutting off the Klebs-Loeffler pirate from the base of supplies which he hoped to establish in the rich inland districts. When his forces have become enfeebled by starvation, the membrane craftily detaches itself and sweeps the invading army down with it into the war-like gastric districts, where the leucocytes have all the advantages of the situation; can massacre the bacilli at their leisure and eat them afterward.

This again coincides with the clinical observation—that so long as the membranes are well developed and *confined to the tonsils*, the constitutional symptoms are usually few and mild, and reinforces the *old* teachings as to the danger of forcibly detaching the membranes, and the *modern* ones as to the harmfulness of too frequent swabbings. It also fits in with the fact that many of the most rapidly-fatal cases are attended by the formation of very little membrane, or of only a thin pellicle, as is usually the case in nasal diphtheria, where both the fixed cells and leucocytes seem simply overwhelmed by the virulence and rapid production of the toxins before they have time to form a membrane.

Nature is wonderfully skilful in guarding her weak points, and although, as the little girl remarked of boils, "there's no *real good* place to have them," yet if we may be allowed so to express ourselves, if we *must* have diphtheria, there is probably no safer place to have it attack the internal surface of the body than the tonsil.

ECHOES AND NEWS.

THE State Senate's Cities Committee is considering the proper location for a hospital for the exclusive use of scarlet-fever cases in New York City. One hundred thousand dollars have been subscribed toward its erection by private individuals.

THE late Mrs. A. R. Aspinwall leaves her whole estate, valued at three millions, to the Hospital of the Protestant Episcopal Church of Philadelphia. The will is liable to be contested by her niece.

THE oldest medical recipe, according to a French medical journal, is that of a hair-tonic for an Egyptian queen. It is dated 4000 B. C., and directs that dogs' paws and asses' hoofs be boiled with dates, in oil.

AN unfortunate altercation is reported to have arisen between the Post Surgeon at Jefferson Barracks, Mo., and his assistant. The court-martial has sentenced the latter to suspension from rank and confinement to post-limits for three months.

THE usual complaint is that the ambulance-surgeon does too little too late, but in the recent case of Babcock, the Harlem Hospital seems to have promoted a young doctor who did too much too soon. Every complaint against the ambulance-service could easily be overcome by a little wholesome discipline.

AT the annual meeting of the Board of Directors of the New York Post-Graduate Medical School and Hospital the following officers were re-elected for the ensuing year: President, Dr. D. B. St. John Roosa; Vice-President, Dr. Andrew H. Smith; Treasurer, Dr. Bache Emmet; Secretary, James L. Skillin.

DR. ELIZA M. MOSHER, of Brooklyn, was recently appointed Woman's Dean and Professor of Hygiene of the Literary Department of the University of Michigan, at Ann Arbor. She has long been a prominent member of the profession, and is now Vice-President of the Pathological Society of Brooklyn.

THE experiment of bicycle-wheels for the Brooklyn ambulances is being put to practical test. Although each wheel represents a cost of fifty dollars, the saving in the item of repair, it is thought, will more than offset this, to say nothing of the increased comfort, and perhaps diminished mortality of the patients.

AN amendment to the Sanitary Code of New York City was recently passed and will go into effect in about a week, requiring all milk-dealers, both wholesale and retail, to provide themselves with a licence. To obtain this they must give the Health Board evidence that their business is conducted strictly in accordance with their rules regulating the milk-supply.

DR. HUNTER MCGUIRE, of Richmond, Va., who is an honorary member of the State Medical Societies of Virginia, West Virginia, and North Carolina, offers a prize of one hundred dollars to be awarded at the next meeting of the Virginia Medical Society in October, 1896, for the most successful essay on "The Status of Serum-therapy." Competition is restricted to members of the societies mentioned.

THERE are 1500 registered physicians in the State of North Carolina, each of whom pays a State tax or licence-fee of $10 per annum; 465, or about one-third, are members of the State Medical Society. The next Legislature will be asked to appropriate the amount of this tax, $15,000, to the establishment of a State vaccine-farm, with provision also for the cultivation of diphtheria-antitoxin.

DR. EDWARD WIGGLESWORTH, of Boston, died there January 20, 1896. He was born in Boston in 1840, and was graduated from the Harvard Medical School in 1865. He served in the Medical Department of the Army for two years during the Civil War. Dr. Wigglesworth spent five years in Europe studying skin-diseases. He founded the Boston Dispensary for Skin Diseases in 1872.

AT an expense of $35,000 for text-books relating to the evils of alcohol and tobacco, the public schools of New York City are prepared to begin the course of forty lessons prescribed by the "Ainsworth Law," which passed the Legislature last year. This Act, which has been contemptuously called the "Jag" Bill, has been the subject of much ridicule, and efforts are now afoot for its early repeal.

AT the annual meeting of the New York County Medical Association, held Monday evening, January 20, 1896, the following officers were elected: President, Dr. Joseph E. Janvrin; Vice-President, Dr. Herman J. Boldt; Recording Secretary, Dr. P. Brynberg Porter; Corresponding and Statistical Secretary, Dr. Nathan Gross Bozeman; Treasurer, Dr. John H. Hinton; Member of the Executive Committee (to serve for four years), Dr. John Shrady.

DR. CASSANOVA, of Bourges, calls attention to the dangerous qualities of cotton-flannel, an article in constant use, especially in the apparel of women and children, and cites three recent cases occurring in his practice in support of his observation as to the highly inflammable nature of this fabric. It is not easily ignited by contact with a live coal, but the blaze of a match or lamp will cause it to flash like gunpowder. His warning in this matter is very timely and important.

A CONCENTRATED antitoxin has been produced by the New York Board of Health. Whereas the serum prepared by Behring and designated by him as Nos. 1, 2, and 3, contained respectively 60, 100, and 150 antitoxin-units per cubic centimetre, the Department is now ready to dispense what it will indicate as No. 4, with a strength of 200 antitoxin-units to the cubic centimetre, No. 5 representing 300, and No. 6, 400. In using these it will be necessary, of course, to reduce the dosage in accordance with the increased potency of the new products.

DR. MARMOREK, a young Viennese physician, after four years of research, has been rewarded by the discovery of a healing-serum to be used against erysipelas and other infectious inflammations of the connective tissue, and also in puerperal fever. It is a product of the streptococcus and is produced like antitoxin. In the hands of the profession of Paris it has given rather promising results. Dr. Chantemesse has tested its efficacy in 500 cases of erysipelas, in which the mortality was 2.59 per cent., while 500 other cases treated by the other approved methods of the present day gave a mortality of 3.79 per cent.

A WELL-KNOWN Philadelphia physician, whose name need not be mentioned for obvious reasons, is in a fair way greatly to increase his already large income through a discovery which he claims to have recently made. The

doctor comes of good old stock, and is quite a figure in Philadelphia's most exclusive society. His discovery, brought about by experiments made upon his own person, is nothing less than the existence of a distinct and separate corpuscle of blue blood. When the result of his researches gets noised about the doctor will doubtless be overrun by Sons of the Revolution, Colonial Dames, and members of other similar patriotic organizations in which ancestry is necessary. In the near future we may expect to hear: "I say, old chap, come take a peep through my microscope and see my blue blood-corpuscle."—*Philadelphia Record.*

THE State Commission in Lunacy has appointed Dr. Ira Van Gieson, of New York, to the position of Director of the Pathological Institute of the State Hospitals for the Insane, which has recently been established. Dr. Van Gieson was selected after a special competitive civil-service examination, which embraced a series of questions in general pathology, minute and pathological anatomy of the nervous system, technique and methods of neural investigation, and the lines of research to be applied to the study of the pathology of insanity. The laboratory, which is to be maintained for the benefit of all the State hospitals, will be conducted on a scale which has not hitherto been undertaken by any State or country, the aim of the commission being to provide for an exhaustive study of all the morbid conditions that underlie mental diseases from the standpoint of cellular biology, which is now elevated to the dignity of a special science; also to provide instruction in brain-pathology and allied subjects for the medical officers of State hospitals. Official bulletins representing the progress of the laboratory and clinical work of the State hospitals will be issued quarterly.

THE MEDICAL NEWS is glad to bring to the notice of its readers the following appeal for the perpetuation of the memory of one of America's greatest scientists:

The Leidy Memorial Fellowship in Anatomy.

It has seemed unjust to many that there is no suitable memorial to perpetuate the name of Joseph Leidy, the great scientist and teacher. A committee has therefore been organized from among his old students to raise whatever money may be necessary for the accomplishment of this object.

There is no idea more suitable, no testimonial more practical, or none which would appeal more to the judgment of the great investigator himself, than the establishment of a Fellowship in Anatomy, the great division of medicine which he loved so well. As the University of Pennsylvania was the scene of the greater part of his labors, the committee has thought it best to establish the Fellowship in that institution.

The creation of the Fellowship will not only perpetuate the name of Leidy, but will enable some practical working anatomist to carry on original work in the University, and to utilize the vast collection of material which is deposited in the Wistar Museum.

Thirty thousand dollars will put such a Fellowship on a permanent working basis, it being intended that the income from this sum should be paid to the Fellow, thus enabling him to pursue his studies with the assurance that his daily wants will be provided for. We appeal to you, therefore, as lovers and admirers of the gentle, humane scientist, whose achievements have made his name familiar on two continents, to aid us by subscribing to this fund.

The movement is a general one, and if you desire further information in regard to the purposes of this memorial, and the regulations which will govern it, we will be glad to communicate with you.

Communications and remittances should be addressed to the Secretary and Treasurer.

DR. J. HOWE ADAMS,
1523 Locust Street,
PHILADELPHIA.

THERE has been in Duluth an epidemic of about 1000 cases of typhoid fever, with 30 deaths, caused, it is believed, by the infection of the water. An inquiry disclosed the facts that the intake of the water company in the adjoining great lake was only 359 feet from the shore, was in a filthy condition, and was situated about 800 feet from the mouth of a large sewer. It appears that the superintendent himself has for a year or two procured water for his family from a spring several miles from Duluth. The city now compels the company to supply spring-water to consumers without additional cost. The supply is said to be abundant and the quality of the water pure and excellent.

DRS. BIGGS and PRUDEN have made to the New York City Board of Health the following report and recommendations, which were adopted at the last meeting:

"It has been for a long time well known that the expectoration of persons suffering from laryngeal or pulmonary tuberculosis (consumption), pneumonia, influenza or la grippe, and from diphtheria, contains the specific germs of those different diseases, and is capable of inducing those diseases in others.

"There is, furthermore, much evidence that a similar condition exists in certain more readily communicable diseases, such as scarlet fever, measles, and whooping-cough.

"In regard to some of these affections, the danger from the expectoration in public places is, of course, small, as the patients are ordinarily confined to their homes during the infectious period. But this is not universally the case. It has long since been shown that the chief means for the transmission of consumption is the dried and pulverized sputum of persons suffering from this disease.

"Diphtheria, influenza, and grip are also easily communicated in this way during certain stages of the disease. Catarrhal affections may also be communicated through dry spittle mixed with dust.

"These germs are liable to be gathered on the feet and on the skirts of women and taken into private houses, where the most perfect ventilation will not stay their effect.

"We believe that the time has now arrived when the people of the city of New York will heartily support the adoption of such sanitary measures as may seem necessary and expedient for the abatement of this widespread nuisance and source of danger.

"We would recommend the following resolutions:

"*Resolved*, That notices be posted in all public places and in all surface and elevated cars in this city, signed by the Board of Health, warning passengers against ex-

pectoration upon the floors of these conveyances; and, further, that similar notices be posted in the stations of the elevated roads, warning against expectoration upon the platforms and stairs or on the floors of the stations.

"*Resolved*, That similar notices be posted in the halls and assembly-rooms of all municipal and Federal buildings in the city.

"*Resolved*, That the municipal authorities be requested to provide sufficient and proper receptacles for expectoration in such public places as are in their control, and that the managers of the elevated roads be requested to provide similar receptacles sufficient in number for their stations and platforms, and that in all cases these receptacles shall be kept in a cleanly condition.

"*Resolved*, That the officers of the Manhattan Elevated Road be requested to give peremptory orders to their guards to restrain from and to prevent, so far as possible, expectoration from trains into the streets, and to secure the inforcement of these orders."

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 7, 1896.

EDWARD D. FISHER, M.D., PRESIDENT, IN THE CHAIR.

PROGRESSIVE MUSCULAR ATROPHY.

DR. G. M. HAMMOND reported a case of progressive muscular atrophy beginning in the facial muscles. He said that many such cases were looked upon with suspicion, but in this instance the history was so clear that he felt the diagnosis was correct. The photograph exhibited had been taken about one year ago. The patient was a middle-aged woman, who at one time was exceedingly vigorous and muscular, and weighed one hundred and eighty pounds. She weighed over one hundred and sixty pounds prior to the advent of this disorder. The family history was excellent, there being no nervous disorder of a serious nature. Fourteen years ago, while a nurse, she had contracted some skin-disease which had resulted in the development of a number of abscesses. About two years ago she began to notice a hollowing of the left cheek and temple, and this had increased until at the present time the atrophy was very marked. The next thing noticed was a weakness of the arms and legs and atrophy of the muscles in these parts. The paresis and atrophy seemed to affect both arms simultaneously, and later both legs. Quite recently the atrophic process had begun to affect the right side of the face. He had first seen her in October, 1894, at which time all muscular efforts were performed with difficulty; fibrillary twitchings could be observed on the left side of the face, and less frequently in the upper and lower extremities. The electrical reactions were normal in quality, but reduced quantitatively. There were no disorders of sensibility, except that at times there had been some rheumatic pains in the neighborhood of the knee-joints. At first the reflexes were exaggerated, but at the present time the knee-jerks are less active than when first seen. The main point for consideration was whether this was a primary myopathy, or whether it was of secondary origin. The fact that it began in the face might lead one to suppose that it was a primary atrophy, but it should be remembered that this disorder began in the latter half of life, there was no family history of this disorder, and the distribution did not correspond to that which was observed in the primary disorder. Moreover, in primary myopathy the muscles of the forearm and leg would escape the atrophic process, whereas in the case presented these muscles were all involved. The case was chiefly of interest from the situation of the primary points of atrophy, which he considered to be very unusual indeed. The case was unusual in that the muscles were not affected in groups, but it did not follow the course of the dystrophics, and it seemed to him that the case must be of central origin. He thought it was not a case of progressive facial hemiatrophy, because there were no changes in the bones or in the skin, and because other parts of the body were involved, and the other side of the face was already beginning to be involved. The process was evidently progressive; the patient was decidedly weaker than a year ago.

JACKSONIAN EPILEPSY; OPERATION.

DR. HAMMOND also exhibited a man who had had Jacksonian epilepsy, and had been operated upon several months ago by Dr. Abbé. His attacks had come on with a sensory aura in the hand. He had had as many as fifteen or more convulsions a day. The operation was done on the left side of the skull last March. On removing the bone, the operator had found a circumscribed area of pachymeningitis, and a considerable adhesion of the membrane underneath. A piece of thin rubber tissue had been inserted after separating the adhesions. The bone had then been replaced, and the wound closed. There had been no convulsions since this operation. Prior to it the bromides had had no effect on the attacks; since the operation these remedies had been given. Quite recently the aura had returned, but there had been no attacks. The speaker said that he could not see the advantages of using the rubber tissue, which in this case had been employed in lieu of gold-leaf. There was a well-marked history of syphilis, and this was considered to have been the origin of the disorder.

RAYNAUD'S DISEASE.

DR. A. WIENER exhibited a man who had been referred to him by Dr. Goldstein. Nine years ago the patient had had a fracture of the left forearm with no accident to account for it. Iodide of potassium was necessary in addition to splints to secure proper union. Later one of his toes had become carious and had been finally amputated. The great toe was similarly affected subsequently, but under local and constitutional treatment this too healed. Inquiry showed that eight years ago this man had been a brass-polisher. At the time of the original fracture there had been no pain. A few months after this he had developed severe pains over the chest and forearm. He then changed his occupation, and after this was exposed a great deal to the weather. At the present time the same gangrenous process which had been present in the toes was going on in the fingers of one hand. This history, the speaker said, made it evident that the patient was suffering from Raynaud's disease. He had excluded syringomyelia, because there

were no sensory disturbance and no pain. There was no sugar in the urine. He expected to put this man to bed and pack his feet in cotton. Constitutional remedies would, of course, be employed.

DR. C. A. HERTER said that there could be little question regarding the diagnosis. As to the local condition and the sclerosis of the vessels, he thought it was secondary to the extraordinary changes in the bloodvessels.

DR. JOSEPH COLLINS said that he also felt that there could be no doubt about the diagnosis, and he also agreed with the last speaker regarding the relation of the changes in the vessels to the present symptom-complex. He had seen two cases of Raynaud's disease during the past year. The administration of iodide of potassium and nitroglycerin—the treatment usually recommended—he considered rather dangerous unless carried out cautiously. The only treatment apparently of service was placing the patient in the horizontal position for a long time, together with the administration of moderate quantities of water and measures to maintain vascular equilibrium. Where it was possible the patient should be sent to a climate which would admit of his living outdoors almost all the time. In looking up the literature of Raynaud's disease he had been surprised at the statement made by several operators that this was an incurable disease. Personally he was of the opinion that Raynaud's disease particularly, if not associated with marked changes in the vessels, gave an exceedingly good prognosis, provided the patient could be under control.

DR. HIRSCH did not think that Raynaud's disease, as such, was a sufficient diagnosis. It was only a collection of clinical symptoms which, it had been shown, might be due to various anatomical lesions—to disease of the bloodvessels, disease of the peripheral nerves, to central lesions, and, in some instances, to pure hysteria. We could not say that the prognosis was good or bad, for it depended upon the particular underlying condition.

PARÆSTHESIA OF THE EXTERNAL CUTANEOUS NERVE.

DR. HIRSCH presented a man, fifty years of age, who had had syphilis eighteen years ago, and had indulged liberally in alcohol. Two months ago, after a shipwreck and much exposure, he had arrived in this country. At the time he was wrecked, for about one hour a considerable weight had been borne by one leg, and shortly after this he had noticed a peculiar sensation on the outer side of this limb, the left, about four inches above the knee. It covered an area the size of the palm, and was never noticed at night, or while reclining or sitting. The sensation was especially aggravated by cold. It was not like any ordinary pain. According to the patient's description, it was a sort of burning sensation, or a "burning cold," as he expressed it. Examination showed no change in the electrical reaction, and no evidence of disease with the exception of a diminution of the thermal sense. The case was, therefore, a paræsthesia in the area of the external cutaneous nerve. The speaker said that a number of these cases had been reported last March by Roth, and a few days later Professor Bernard, of Berlin, had independently published several cases of this kind. A number of other cases had since been reported, and many of them had occurred in physicians. One distinguishing feature was the indefinite character of the paræsthesia, and the fact that it was never noticed when the patient was reclining or sitting. Acute infectious diseases had been mentioned in connection with the etiology of the condition. In the case presented, it was possible that syphilis and alcoholism might be considered as predisposing causes, while the prolonged pressure and the exposure at the time of the shipwreck might be looked upon as exciting causes.

TWO CASES OF TUMOR OF THE SPINAL CORD UNACCOMPANIED WITH SEVERE PAIN.

DR. PEARCE BAILEY read a paper with this title. He said that the total number of reported spinal tumors was not large; he had only been able to find 130 in all. His cases were presented merely as a contribution to a subject which merited careful observation.

The first case was a female, fifty-five years of age, who had had a good family and personal history. Last June she had been attacked with a rapid pulse and increased temperature and pain all over the body. There was also albuminuria. Death occurred sixteen days after coming under observation. The autopsy showed œdema of both lungs and marked atrophic nephritis. On the posterior and internal surface of the dura mater was a tumor, three-fourths of an inch long, one-eighth of an inch wide, and elevated about one-tenth of an inch above the surface of the membrane. It was directly opposite the posterior longitudinal fissure, was extremely hard, and finely lobulated. Microscopical examination showed a connective capsule, but the substance of the mass was subdivided by many fibrous trabeculæ. The death of the patient had been due entirely to one of the attacks of pulmonary œdema to which those suffering from Bright's disease are liable.

The second case was a female, twenty-nine years of age. No history of syphilis could be obtained. In 1889 laparotomy had been performed, and a small tumor of unknown nature removed. A second laparotomy had been done and another tumor removed some months later. Subsequently a tumor had been extirpated from the ribs, but it was impossible to obtain any history as to the nature of these growths. In 1889 she developed paralysis and numbness of all four extremities, which lasted ten months. In July, 1883, there had been another similar attack of paralysis. At this time she had also had cystitis. She was treated with strychnine and electricity, and was able after a while to walk out of the hospital. She was readmitted in 1895 with another attack of paralysis. On examination her mentality was excellent, both pupils reacted to light, but the left pupil was considerably smaller than the right; the right side of the face was pale as compared with the left; there was well-marked extensor paralysis of all four extremities. There was a moderate amount of atrophy; both knee-jerks and elbow-jerks could be elicited. There seemed to be some blunting of the tactile sensibility. The urine gave evidence of nephritis. She stated very positively that she had never been subject to any severe pain, and she certainly had no pain at the time of examination. She could move her head freely in all directions, and without any discomfort. There was no tenderness over the vertebral column. The absence of anæsthesia made the location of the tumor difficult, and her exhausted condition made operation impracticable. She died in July, 1895, from pulmonary œdema and suppression of urine. The autopsy showed extensive adhesions of the lungs and an old pulmonary

cavity. The spleen and liver were enlarged. The ureters were dilated and the kidneys showed pyelonephritis and large calcareous concretions. The brain, with the exception of atheroma of the arteries, was apparently normal. On exposing the dorsal surface of the cervical portion of the cord this appeared to be abnormally prominent, and on its removal a tumor was found, which was slightly adherent to the cord. It was an irregular, quadrilateral-shaped mass limited almost exclusively to the ventral side, and affecting the nerve-roots, one, two, three, and four on the right side, and one, two, and three on the left side. The dura itself was thickened. The cord was pressed upon anteriorly and posteriorly, causing it to bulge so that the posterior roots were considerably separated. Sections of the tumor and of the cord were made and stained and exhibited to the Society under the microscope. The tumor was found to spring directly from the external surface of the dura mater. The tumor consisted of an outer zone of fibrous tissue, inside of which was a zone of polyhedral fusiform cells. The remainder of the tumor was in a condition of cheesy degeneration. The picture was a typical one of gumma with excessive degeneration. No tubercle-bacilli were found. Above the tumor was a moderate ascending degeneration. The cord opposite the tumor was not much compressed. The anterior horns were normal as regards their shape and constituent elements. The nerve-roots, as shown in the section, presented no evidence of degeneration. An area of connective tissue surrounded the bloodvessels and apparently indicated the vascular origin of the tumor in the cord. The possible vascular origin of the process explained satisfactorily the absence of pain.

A third might be added, which had been reported in *Brain* some years ago. Here the tumor had extended from the origin of the fifth cervical to the first dorsal nerve, and lay chiefly posteriorly. The nerve-roots were compressed and atrophied, and there were the ordinary ascending and descending degenerations. The symptoms caused by the new growth had been paralysis and loss of sensation, but without the pain characteristic of spinal tumor. These symptoms had existed about three months. The absence of pain was emphasized in the report of this case. Dr. Bailey said that an attempt to account for the absence of pain in these three cases was difficult. All were of slow growth, and pressed but slightly on the cord, and two of them were yielding. The points where the pressure was applied or the rapidity of the growth seemed to be of secondary importance, and the position of the tumor with reference to the membrane appeared to influence but little the occurrence of pain. The most important factor was the consistency of the tumor—those which softened and degenerated most easily were the least liable to be accompanied by pain. His conclusions were: (1) That it was probable that tumors of the spinal cord were more frequently painless than was commonly supposed; and (2) that the pain was indicative rather of its nature than of its situation.

DR. B. SACHS said that this question of pain as a diagnostic symptom of tumor of the spinal cord had only been recently discussed before this Society. At that time he believed he had been in the minority in stating that he did not think so much stress should be laid upon this symptom as had been generally done; hence, he was glad to hear of those cases which confirmed his view. The symptom, pain, would naturally arise in those cases in which there was a very large tumor on the ventral surface actually pressing the cord against the posterior surface; it would arise still more frequently if the tumor invaded the posterior root-fibres. He would again emphasize the fact that root-symptoms were important in the earlier stages of tumor, whether they were of the sensory kind or of the atrophic order. In the majority of cases pain was, of course, present as an early symptom. In addition to the root symptoms, the next important point was that the symptoms in the majority of cases were apt to be unilateral, with a rapid involvement later of both halves of the cord; there was not that symmetry in the symptoms which was usually observed in the subacute affections of the spinal cord.

DR. LEONARD WEBER remarked that these tumors described in the paper were not tumors *of* the cord, but were *upon* the cord. In 1891 he had met in Germany a physician who had had a large experience with tumors of the spinal cord. The history of these cases showed that there had been no special pain present.

DR. C. A. HERTER thought that without doubt these extradural tumors should be classed as tumors of the spinal cord, for when they produced symptoms they did so by their influence on the cord and its nerve-roots. He also thought that it was pretty well established that extradural tumors were much less apt to produce pain than intradural tumors. The cases so well reported in the paper were certainly valuable additions to this subject. Some years ago he had gone over the subject of solid tumors of the spinal cord, and had found only twenty-six cases, three of them having been in his own practice. In several of these there had not been much pain, at least in the beginning of the disease. A possible explanation of this might be found in the fact that the origin of a tubercle was usually in the substance of the cord itself—that the tubercular process began by the deposition of tubercle-bacilli in that portion of the cord which afforded the best nutrient basis for the bacilli. In one of his cases it was quite evident how the process had extended by a narrow line of bloodvessels into the anterior horn of one side, and had subsequently extended to the white matter. It was easy to see how in a case of this kind there should be no pain. In syphilitic tumors of the cord the process was apt to originate in much closer connection with the pia mater, thus making root-symptoms, or a meningitis involving the circumference of the cord, more liable to occur. He had been impressed with the different character of the symptoms in cases of sarcoma invading the cord from without, and cases of glio-sarcoma starting from within. In the majority of cases of sarcoma of the spinal cord the process was a secondary one, and almost invariably involved the posterior nerve-roots, giving rise to intense pain. Another class of sarcomatous tumors originated about the central part of the cord, and in these there was little or no pain. The reason for the absence of pain in cases of syringomyelia was the early involvement of the sensory fibres.

THE PRESIDENT said that tumors outside of the cord-substance were more likely to cause pain, unless they were extradural; but a tumor within the cord, unless so large as to compress the nerves, could hardly be expected to cause pain. Again, in cases of tumor outside

of the cord the pain was usually of a shooting character, and followed the course of the nerve irritated. The explanation of the absence of pain in the cases recorded in the paper appeared to be due rather to the situation than to the nature of the tumor.

TWO SPECIMENS OF BRAIN-TUMOR, WITH REMARKS ON THE DIFFICULTY OF DIAGNOSIS.

THE PRESIDENT presented a pathological specimen removed from a laborer, fifty-six years of age, who gave a history of an injury to the head when twelve years of age. As a result of this there had been during his boyhood repeated *slight* attacks of epilepsy. Four years previous to his death he had received another injury to the side of the head, and two years later had begun to have definite localized convulsive seizures on the left side of the body. They always commenced with a sensation in the left hand of slight tingling or numbness. This would be followed by a full convulsion involving the left hand and arm, and sometimes the leg. These attacks recurred at intervals of two or three weeks. He had no pain, and gave no history of disturbed vision, and the ophthalmoscope showed no optic neutritis. The only other symptom was a slight paresis on the left side, lasting only a few days, after each epileptic seizure. On examination the gross strength was good; there was some loss of muscular sense; there was some ataxia in the left hand and exaggerated reflexes, particularly of the left patella. There had been no headache. In June, 1895, an ordinary trephine-opening was made, and some adhesions between the dura and skull were found. The attacks ceased for some time after the operation, but when seen by the speaker last October these attacks had returned. A diagnosis had been made of a localized lesion, probably due to pachymeningitis following a trauma and involving the hand-centre. An operation was therefore performed by Dr. Stimson. The dura was found adherent, as had been expected. The operation was attended by much hemorrhage, and followed by great shock, and in a few hours death ensued. At the autopsy a large sarcoma was found, involving the leg-centre and a portion of the arm-centre, and extending a considerable distance back into the parietal lobe.

The second specimen had been removed from a boy, eighteen years of age, having a negative family history. For two years previous to his death he had complained of more or less headache. His gait had been uncertain and staggering, but in no particular direction. He complained of considerable continuous headache. For the last year he had complained of loss of vision. Examination showed optic neuritis and optic atrophy, and the boy was almost blind. There had been no convulsions during this time, but there was a history of one or two attacks of vomiting at long intervals. A diagnosis had been made of tumor of the cerebellum, localized on the left side because of the deafness on the left side, a very slight facial paralysis, and the loss of sensation on the left side. Two or three days before death there were several convulsions with vomiting, and he died in coma. There was at no time any mental dulness or apathy. The autopsy showed, according to the report of Dr. Warren Coleman, a large single cyst containing 73 c.c. of slightly turbid, straw-colored liquid, which had not been coagulated by the formalin, though the cyst-wall was very thin over its upper part. The growth was situated in the left hemisphere of the cerebellum. The liquid apparently contained no albumin, as it did not coagulate on the addition of the commercial formalin or on the application of heat. It did contain mucus. Examined microscopically, the liquid was found to contain an abundance of old blood-cells, well hardened, a moderate number of protoplasmic mononucleated cells, apparently leucocytes, whose proto plasm was filled with highly refracting globules and larger flat cells, mononucleated, resembling endothelium. Strings of mucus were found in abundance. The liquid contained something which turned Fehling's solution a rich purple, and which threw down a red sediment after twenty-four hours. The growth was a glioma.

DR. SACHS referred to a case, seen many years ago, in which there had been attacks of hemiplegia and intense frontal headache. A diagnosis had been made of gumma, but the autopsy had shown a glioma very much like that presented. All the symptoms had disappeared for about four months under the use of antisyphilitic treatment.

DR. L. STIEGLITZ said that the first case reminded him of one operated upon about a year ago in which a gliosarcoma had been found. In this case there had been very few symptoms present for months. One very valuable symptom had been the exquisite tenderness to tapping the skull. He believed that this symptom could have been elicited in the case just reported because of the presence of adhesions. It was unfortunate that in the first operation the attending surgeon had made the trephine-opening so small—altogether too small to admit of proper exploration. The second case closely corresponded to one he intended soon to report, in which there had been deafness on one side. The case also brought out the malignity of many tumors of the brain.

DR. HERTER remarked that the long duration of the condition in the first case was a point to be considered in connection with the presence of such few symptoms.

SPECIMEN SHOWING MULTIPLE GROWTHS IN THE BRAIN OF A CHILD.

DR. JOSEPH COLLINS presented a specimen from a child who had presented a condition similar to that formerly described in the books as spurious hydrocephalus. The patient was admitted to Dr. H. D. Chapin's wards in the Post-Graduate Hospital, and the diagnosis of tumors of the brain pressing on the third ventricle was made: one situated near the posterior commissure, one pressing against the head of the nucleus caudatus, while another seemed to include the left anterior quadrigeminal body. Microscopical section of the new growths showed them to be tuberculous. On the inferior surface of the cerebrum was a new growth about the size of an American walnut, and on opening the brain four other growths were found.

DR. C. L. DANA described the clinical history of this case. He said that the child was about two years old, and had been perfectly well up to last August, when there had been a sharp attack of diarrhœa. After this the child became sleepy, and remained all the time with the eyelids closed. The was no paralysis, and no pain and no convulsions. About three months later he had examined the child. At that time it was cataleptic; there were no paralyses; no sensory symptoms; it could

hear and could swallow; there were double ptosis and slight nystagmus; there was no ophthalmoplegia except the double ptosis. The hebetude deepened, but there were no convulsions. The child died in the latter part of December. The speaker said that he had tapped the spinal cord in this case and removed two drachms of clear fluid which, on examination, showed no evidence of tubercle-bacilli. The autopsy showed these multiple tubercular tumors. He had made the diagnosis of tumor of the midbrain. He believed that most of the symptoms were due to the growth involving the corpora quadrigemina. He had been particularly interested in this marked somnolence in cases in which there was pressure on the third ventricle or on the corpora quadrigemina.

Dr. Sachs said that there was a marked resemblance between this case and one reported by him in an article on disease of the midbrain region. In the case referred to, there had been an increased apathy, but owing to its tubercular nature he had attributed this to the stage of the disease. He had been surprised to find also in his case several tumors in the cerebellum as well as a tumor in the midbrain region.

Dr. W. B. Noyes presented a specimen removed from a man who four years ago had been crushed between two cars. The pressure had been exerted at about the level of the first lumbar vertebra. No paralysis or fracture had resulted, but he had suffered from shock, and had been confined to bed for two months. About one year ago he had had an apoplectiform attack, characterized by blindness and deafness and paralysis of both legs, lasting for twenty-four hours. When seen by the speaker, three weeks ago, there had been spastic paraplegia, marked ataxia, increased knee-jerk and ankle-clonus, great tenderness all over the body, but especially in the head. A diagnosis had been made of brain-tumor. Death occurred from a sudden paralysis of respiration. The autopsy showed an endothelioma of the dura mater occupying the place of the occipital lobe. The tumor was irregularly kidney-shaped, with its broadest diameter from side to side. Its weight was 300 grammes. It was hard, nodular, and did not infiltrate the brain-tissue. The spinal cord was examined, but nothing abnormal found.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninetieth Annual Meeting, Held in Albany, January 28, 29, and 30, 1896.

(By Telegraph to The Medical News.)

The Ninetieth Annual Meeting of the Medical Society of the State of New York was held in Albany, January 28, 29, and 30, 1896, Roswell Park, M.D., of Buffalo, President, in the chair.

First Day—January 28th.

The President in his inaugural address referred to the revival of the *Index Medicus*, the advantage to the profession of the valuable collection of books known as the medical department of the State Library, and to other topics of general interest. He referred particularly to a recent court-decision by which a physician, when bringing suit for services, was debarred from disclosing the nature of such service.

The first paper was a note on the

use of permanganate of potassium in diseases of the skin.

Dr. L. Duncan Bulkley, of New York, said that he had found accidentally from a patient that a 1 or 2 per cent. solution of permanganate was an excellent local application to relieve pruritus. It produced a brown stain lasting some time, and by its oxidizing action caused a marked reduction in the thickness of patches of diseased skin.

water and its relation to disease.

The discussion was opened by Dr. W. P. Mason, of Troy. He said that peaty water or water from low-lying lands sometimes caused mild diarrhœa; but as yet little was known as to its relation to disease. He quoted as an example of the disastrous effects of an impure water-supply a severe epidemic of cholera occurring at Messina, Sicily. The water-supply was found to have been contaminated by the washing of clothing, and also by the close relation of the sewers and water-mains, both being of unglazed material. By prohibiting the use of this contaminated water and substituting pure water from another source the epidemic collapsed as if by magic. Observations both in England and in this country showed that typhoid fever frequently followed heavy rains when they succeeded spells of drought. He then considered the question of whether it paid to have a pure water-supply, assuming the value of a human life to be, as had been conservatively stated by E. F. Smith, two thousand dollars, and, computing the loss of time in the cases that recovered, he concluded that the total yearly loss to the city of Albany alone was practically equivalent to a tax of two hundred thousand dollars.

Dr. Lewis Pilcher, of Brooklyn, in the discussion, said he considered it an opportune occasion to refer to a bill now before the Legislature relative to the cutting of ice in rivers. The Legislature had requested the opinion of the Society on this matter, and the matter had been referred to the Committee on Hygiene. He desired now to present the report of the Committee, viz.: "That it was the opinion of the Committee that it was perfectly proper to allow ice to be cut from rivers under certain reasonable restrictions." This opinion was based on the well-known self-purification of running streams. The bill proposed very unwisely, it was thought, to prohibit absolutely cutting of ice from all rivers.

Dr. A. Jacobi, of New York, heartily approved of the Committee's report, for it should be remembered that in addition to this self-purification alluded to, foreign matter contained in water was constantly sinking as the ice was being formed at the surface.

Dr. V. R. Merrill referred to a sudden outbreak of typhoid fever this winter in the Chemung Valley, after some of the ice had already been cut and stored for use in the following summer. As the typhoid bacilli had been readily detected in the river-water, the question naturally arose as to the probability of this ice having also been contaminated.

Dr. M. A. Crockett, of Buffalo, read a paper on

sepsis of the newborn.

Prognosis in these cases was most unfavorable when gastro-intestinal disorder was one of the prominent evi-

dences of sepsis. There were three cases reported, and statistics were given from a large series of cases, showing the advantages of the careful and systematic aseptic dressing of the umbilicus.

DR. A. JACOBI emphasized the skin, mouth, and anus as frequent paths of infections. The liquor amnii was a common source of infection. Slight denudations of the mucous membrane in the mouth of the newborn afforded easy means of access to micro-organisms.

DR. CHARLES JEWETT, of Brooklyn, said he had never seen a case of sepsis in the newborn in which the infection had occurred through any other channel than the umbilicus.

DR. CHARLES JEWETT, of Brooklyn, read a paper on

THE QUESTION OF PUERPERAL SELF-INFECTION.

Many careful and distinguished observers were quoted as opposed to the probability of self-infection, some of these opinions being based on the belief that the acidity of the vaginal secretion was inimical to germ-life. All childbed infection in previously healthy women was by contact. The most carefully prepared statistics showed that antepartum douching was unnecessary, if not positively harmful.

DR. A. WALTER SUITER, of Herkimer, presented

A MEDICO-LEGAL NOTE,

the object of which was to show that although it was reasonable to suppose from well-established physical laws that a bullet, owing to the heat produced by the friction of impact, could not carry infection into a wound, recent experiments of Dr. Legard, of the U. S. Army, showed that this supposition was incorrect. This observer experimented on animals with bullets infected with recent cultures of anthrax, and found that these animals died with symptoms of anthrax-infection.

DR. J. L. HEFFRON, of Syracuse, read a paper entitled

SHALL THE STATE ATTEMPT TO CONTROL THE SPREAD OF TUBERCULAR DISEASE?

which will appear in full in a later issue of THE MEDICAL NEWS.

DR. A. JACOBI said that in Europe it had been found that 28 per cent. of those afflicted with tuberculosis could be restored to usefulness, and that insurance-companies in certain countries of Europe had learned that it was cheaper for them to establish and run sanitaria for those of their policy-holders afflicted with tuberculosis than to pay the amount represented by these policies if these individuals were allowed to die.

DR. E. F. BRUSH, of Mount Vernon, said that his investigations had showed him that the only people on the face of the earth who enjoyed immunity from tuberculosis were those who did not domesticate the cow.

A discussion followed on

EARLY AND LATENT SYPHILIS IN INFANTS AND YOUNG CHILDREN.

DR. GEORGE T. ELLIOT, of New York, took up the question of hereditary syphilis. He said that the syphilitic infant might at birth be well nourished, and remain so for some weeks, and then suddenly die without having given any signs indicative of that disease. In other cases, the child would begin to lose flesh after about three months, and then present the usual evidences of syphilis. The cutaneous lesions were usually more hyperæmic and diffused than in acquired syphilis. The bullæ on the palms and soles were peculiarly characteristic, and were distinguished from simple pemphigus by the fact that the latter has no special localization, being found on all parts of the body, appearing epidemically and running a definite course in a few days. Condylomata at the corners of the mouth were also diagnostic of syphilis, as were also the bone-lesions found at the epiphysis of some of the long bones. Dactylitis, however, could not be considered pathognomonic, as tubercular lesions of a similar character were sometimes found. The deafness of hereditary syphilis, so much insisted upon by Hutchinson, usually occurred suddenly and was persistent. The well-known "Hutchinson-teeth," it should be remembered, were observed in the second set of teeth.

DR. B. SACHS, of New York, discussed the

NERVOUS MANIFESTATIONS OF SYPHILIS.

He said that syphilis of the nervous system was apt to be a cerebro-spinal affection, and might involve a small area of the brain or of the spinal cord. It might be briefly stated that cerebro-spinal syphilis was an extensive disease of slight intensity. A child with mild palsy, symptoms of cortical irritation, and imperfect speech might be reasonably considered to be suffering from cerebro-spinal syphilis. In more than two hundred cases of infantile palsies, in which Dr. Peterson and he had carefully inquired into the etiology, it had been found that only one case was due to syphilis. Among the spinal manifestations of hereditary syphilis was a spastic paraplegia, coming on late, and often associated with palsies.

DR. L. DUNCAN BULKLEY said that hereditary syphilis was not so common as formerly. Syphilitic infants should be treated at the earliest possible moment, for, as Fournier said, "Nothing is so dangerous to its surroundings as a syphilitic child." The speaker expressed the belief that the best treatment was inunction with a half-strength mercurial ointment, and this treatment, as in the adult, should be persisted in for two or three years. The syrup of the iodide of iron was a most important remedy in infantile syphilis.

DR. EDWARD D. FISHER, of New York, concurred in the opinion expressed by the last speaker regarding the treatment, except that where "mixed treatment" was employed or iodide given, he preferred to give the iodide separately from the iron. Again, it should be remembered that in the late cases the children did not always need iron.

DR. GAYLORD P. CLARK, of Syracuse, read a paper on

THE EQUILIBRIUM-FUNCTION OF THE EAR,

in which some recent physiological investigations and the inferences from them were presented. In brief, it had been found by experiments on the dogfish that when this fish was rotated in certain planes and the ampullæ of certain semicircular canals stimulated, or their nerves divided, there resulted certain movements of the eyes and fins, indicating an effort to restore the fish to its normal resting position. Section of the nerve on one side appeared to cut off the normal impulses, and left normal impulses on the other side unbalanced, so that

the fish received the impression of being turned on one side. The author said that he had succeeded also in collecting considerable evidence going to show that the human ear functionated in a similar manner.

DR. ROBERT H. GRANDIN, of New York, read a paper on

DISEASES OF INTRAUTERINE LIFE DUE TO THE MOTHER.

He said that there was evidence to show that most of the infectious diseases could be transmitted from the mother to the fœtus, but the mode of this transmission was purely one of speculation The anatomy of the placenta showed that probably there was an interchange of material, either nutrient or toxic, in the intervillous spaces. This transmission was effected probably by transfusion or by migration of leucocytes. According to this theory, a healthy placenta only could offer an effectual barrier to the transmission of disease, but it was probable that a perfectly healthy placenta did not often exist.

DR. P. W. VAN PEYMAN, of Buffalo, present by invitation, in a paper on

ECLAMPSIA,

said that the toxins causing uræmia were varied and numerous. In eclamptics the urine had been found less toxic, while the blood-serum was more toxic than normal. Jaundiced urine was exceedingly toxic. His experience in the treatment of eclampsia with veratrum viride had been favorable, provided the pulse had been sufficiently strong to warrant the administration of this drug. Pilocarpin was too depressing in its action. In his opinion many cases of eclam psia died as the result of too heroic medication.

DR. CHARLES W. ELIOT, President of Harvard University, delivered an address on

MEDICAL EDUCATION OF THE FUTURE,

in which he compared the educational facilities of thirty years ago with those of the present day, and also with the greater requirements now demanded of the physician. He said that the old régime had demonstrated the fact that even with poor preparation for the study of medicine it was possible to turn out some very worthy and skilful physicians, but it did not follow from this that the practice was a wise one. The rapid advance in the collateral branches, particularly in the analysis of the urine, in microscopy, and in bacteriology, called for a broader education, not only after entering the medical school, but in the preliminary training. There had been greater improvements in methods of diagnosis than in treatment. The ever-advancing science of preventive medi cine charged the physician of to-day with new and very important duties which required a high degree of intelligence and training.

Thoroughly educated and competent physicians were now needed to fill public sanitary positions, positions which, it need hardly be said, should bring with them adequate compensation. Every physician should be a zealous philanthropist and missionary, and hence there should be not only a full knowledge of preventive medicine, but the physician should possess the requisite moral and intellectual powers. Such a physician could exert a most beneficial influence in checking the violent and unreasoning opposition of such people as the anti-vaccinationists and anti-vivisectionists. In order to obtain this better education demanded by the times, it was necessary that better training should be given in the years between the ages of six and twenty-one, for the four years of education at the modern medical school were already filled to overflowing. Much time was now wasted in our schools. Physicians, he said, could effect a needed reform in this direction if they were less backward about assuming positions as school trustees, where they could do away with the antiquated methods of teaching now in vogue and largely due to the long dominance in school boards of the clerical element. Johns Hopkins University had taken a most important step in the right direction, and Harvard had already announced her intention of following, *i. e.*, the requirement of a degree in arts, philosophy, or medicine of those entering the medical school.

(To be continued.)

REVIEWS.

OUTLINES OF PRACTICAL PHYSIOLOGY, BEING A MANUAL FOR THE PHYSIOLOGICAL LABORATORY INCLUDING CHEMICAL AND EXPERIMENTAL PHYSIOLOGY, WITH REFERENCE TO PRACTICAL MEDICINE. By WILLIAM STIRLING, M.D., Sc.D., Brackenburg Professor of Physiology and Histology in the Owens College, and Professor in Victoria University, Manchester, etc. Third edition, revised and enlarged, with 209 illustrations. Philadelphia: P. Blakiston, Son & Co.

THE well-known *Outlines of Practical Physiology*, compiled by Professor Stirling, for the most part from the standard works on physiologic chemistry and experimental physiology, has reached a third edition and appears in a revised and enlarged form. The success which this book has met with not only in England, but in this country as well, is sufficient proof of its merits as a convenient and satisfactory guide in laboratory-work. The methods for the investigation of the chemic composition and properties of the fluids and solids of the body are clearly and tersely described and adapted for relatively inexpensive chemic apparatus. The same holds true with reference to the methods for performing the fundamental experiments illustrating the physiology of the nervous system and special senses. Some of the experiments detailed here require, however, for their repetition very elaborate apparatus, to be found only in well-equipped laboratories. Every student, however, who is entering on the study of physiology should possess a copy of this manual and repeat, as far as possible, the experiments here detailed. Physicians will find, in a convenient form, all the best methods for the examination of the blood, urine, and secretion generally.

A TEXT-BOOK OF FORSENIC MEDICINE AND TOXICOLOGY. By ARTHUR P. LUFF, M.D., Lecturer on Medical Jurisprudence and Toxicology in St. Mary's Hospital. In two volumes, small 8vo. Vol. I. 416 pages. Vol. II. 334 pages and index. London and New York: Longmans, Green & Co.

THIS is a compact and useful compendium of medical jurisprudence and toxicology. It is illustrated with twelve full-page plates and fifty-seven figures in the text. One of the plates, representing various blood-spectra, is in colors. All the illustrations are well executed and the general typography is excellent.

The matter of the book is well selected and arranged, and follows the usual order of treatises of this character. The toxicology covers over three hundred pages, being all included in the first volume. This is not an undue proportion for so important a subject. Experience in this country shows that physicians are more liable to err in the diagnosis of cases of poisoning, or, at least, to mistake them for disease, than in almost any other field of work. We are glad to note that a considerable space is given to Reinsch's test for arsenic. The ingenious method described for securing the crystalline sublimate on the surface of a glass slip, so that it can be examined under the microscope, will be of much use. Dr. Luff does not think it possible to determine from the measurements of the corpuscles that the blood was positively human blood, but thinks that it is only safe to say that it is mammalian blood. This is a wise and conservative view. Much injury has been done to the cause of expert testimony by the readiness of certain experts to testify positively in this and similar cases in which positiveness cannot be attained.

The treatment of all the topics seems to be excellently proportioned and we consider the work to be a most valuable addition to the literature of the subject.

—

THE DISEASES OF CHILDREN'S TEETH: THEIR PREVENTION AND TREATMENT. A MANUAL FOR MEDICAL PRACTITIONERS AND STUDENTS. By R. DENISON PEDLEY, M.R.C.S., L.D.S. Eng., F.R.C.S. Edin., Dental Surgeon to the Evelina Hospital for Sick Children, London. J. P. Segg & Co., London; S. S. White Dental Mfg. Co., Philadelphia.

As the title-page indicates, this manual is designed for medical practitioners and students, and as such it presents in clear and readable form just the information that is needed in order to understand and treat the ordinary conditions affecting the teeth of children. The contents include chapters on Structure, Eruption, Caries, Palpitis, Periodontitis and its Sequelæ, Irregularities of the Teeth, the Hygiene of the Mouth, and Treatment. The chapter on Oral Hygiene is admirable, and is thoroughly abreast of the modern pathology. Under "Treatment," mechanical and operative procedures naturally are but slightly discussed, but their principles are clearly outlined, and in cases of necessity could be satisfactorily applied by any medical man. Indeed, the author's work is so practical in its scope that dental practitioners might peruse its pages with advantage to their youthful patients. A satisfactory index closes the volume. The illustrations are numerous and add greatly to the value of the text.

—

ELEMENTARY TECHNIQUE IN HISTOLOGY AND BACTERIOLOGY. By ERNEST B. HOAG, A.B., B.S., Instructor in Zoölogy and Physiology, Throop Polytechnic Institute, Pasadena, Cal., and H. KAHN, Pharm. (Mich.), Assistant Demonstrator in Bacteriology, Northwestern University Medical School, Chicago. E. H. Colegron and Co., Chicago, 1895.

A COMPEND of 130 pages for beginners in histology and bacteriology, containing the various methods of staining and preparation of tissue for microscopic study. No attempt is made to introduce descriptive histology. The book is poorly printed, and for a work intended for beginners contains too many technical abbreviations. It is up to date, and will no doubt be useful to those for whom it was intended.

CORRESPONDENCE.

INFLUENCE OF SUSPENSIO-UTERI UPON PARTURITION.

To the Editor of THE MEDICAL NEWS,

SIR: Having recently had some unfortunate experience concerning the influence of suspensio-uteri upon parturition, I feel that it is highly important that this question be settled in an authoritative way as soon as possible. The only way to determine the question is by studying the actual results as seen in the practice of all operators. I will be much indebted to anyone having had a case of pregnancy following suspension of the uterus, if he will communicate the details of the case or cases to me.

Very truly yours,

CHARLES P. NOBLE.

1037 NORTH BROAD STREET, PHILADELPHIA.

THE INDEX MEDICUS.

To the Editor of THE MEDICAL NEWS,

SIR. We ask permission to announce to the subscribers to the *Index Medicus* that the January number, which comprises the literature of December and the beginning of January, is printed and will be distributed in a few days. The "back number," covering the period from May 1 to December 1, 1895, is ready for the printer, but from its extent will require some time before it can be issued.

It is proper to add that it has been found impossible to adhere to the limited number of subscribers first proposed, as subscriptions from distant points in response to applications from friends abroad still occasionally arrive. One, for example, was received to-day from Ceylon through a London friend.

J. S. BILLINGS,
ROBERT FLETCHER,
Editors of *Index Medicus*.

WASHINGTON, D. C., January 23, 1896.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. ARMY, FROM DECEMBER 31, 1895, TO JANUARY 13, 1896.

The appointment of JAMES SPRIGG WILSON to be Assistant Surgeon, with the rank of First Lieutenant, to rank from December 16, 1895, is announced. He will report in person, without delay, to the President of the Army Medical School for Instruction.

Leave of absence for six months, on account of disability, is granted Major CLARENCE EWEN, Surgeon.

Leave of absence for two months, to take effect on or about January 21, 1896, with permission to go beyond sea, is granted Major CURTIS E. MUNN, Surgeon, Benicia Barracks, California.

The leave of absence on surgeon's certificate of disability granted Major JAMES C. WORTHINGTON, Surgeon, is extended six months on account of sickness.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 4, 1896.

January 3, Assistant Surgeons M. S. GUEST and C. P. BAGG ordered to examination for promotion.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, FEBRUARY 8, 1896. No. 6.

ORIGINAL ARTICLES.

HYDROTHERAPY IN TYPHOID FEVER.

BY A. L. BENEDICT, A.M., M.D.,
OF BUFFALO, N. Y.
LECTURER ON DISEASES OF THE DIGESTIVE ORGANS, DENTAL DEPARTMENT, UNIVERSITY OF BUFFALO.

THE Brand method of treatment of typhoid fever, with or without modifications, has been so enthusiastically indorsed in this country by Baruch, Osler, and other eminent clinicians, that it is with some hesitancy that I offer a paper which, though not strictly antagonistic to the immersion-treatment, nevertheless represents strongly conservative views.

We may say, approximately, that at present all the typhoid patients in hospital wards in this country are treated by immersion, and all the private patients by methods that are hydrotherapeutic only to the extent of cool sponging. Such a statement is not literally true, but the exceptions are certainly rare. It is also probably true that though most expressions of opinion heard in societies or read in journals favor the Brand treatment, or its modifications, a secret ballot would show an overwhelming majority of the profession against this method. Neither the discussion nor the vote, however, would be decisive as to the merits of the issue. We must ask, rather, what the opportunities for observation, and what the ability for forming an opinion on the two sides. In Buffalo, with a population of 350,000 inhabitants, we may expect about 500 cases of typhoid annually. Of these, 200 will be treated in hospitals, leaving about 300 cases to be divided among the 500 practitioners of the city. It is obvious, therefore, that the average physician treats a very small number of cases. However, it must be admitted that with the exception of the open country, and a few cities with unusually good water-supply, the figures given do not adequately represent the prevalence of typhoid, and that the private practitioner of the small towns has not only relatively, but absolutely, better opportunities for studying typhoid than has his city colleague. We must also bear in mind that "experience" does not mean a census of cases, that one may acquire more real experience from watching one case than another from treating fifty, and that with equal powers of observation the man who has seen ten cases is almost as well equipped as the one who has had a hundred. All things considered, we must conclude that the question as to the immersion-treatment of typhoid fever has excellent advocates on both sides, so that no one need hesitate to express an opinion through fear of lack of support.

Experience with antipyretic drugs has exploded the old notion that elevated temperature is the essence of a fever. Within a limited range, say between 101.5° and 103.5°, the temperature is not necessarily an index of the severity of the disease, and one of the ablest clinicians of the country has said that an evening temperature of 103° in typhoid may be considered as normal to the disease, and as requiring no interference. Advocates of the strict Brand treatment do not claim that the baths are decidedly antipyretic, but regard a marked lowering of the temperature as throwing doubt on the diagnosis. Others, however, do use the immersion-bath to reduce temperature, and still regard themselves as followers of Brand. To facilitate reference I will number and italicize certain propositions that I would like to submit:

1. *If a temperature becomes so high that it must be brought down (103° or 103.5° and over), antipyretic means should be selected that will produce the least shock. Immersion will rarely fulfil this requirement, even its advocates admitting it to be painful.*

2. *It is bad practice to cool a fevered body by plunging it into ice-cold water as one would cool the contents of a hot test-tube. In general, cool sponging of one part of the body at a time is to be preferred. Occasionally an antipyretic drug, such as acetanilid, phenacetin, phenocoll, or lactophenin, may be used.*

3. *Any bath below the temperature of the body has the power of abstracting heat, and if it produces chilliness or symptoms of mild shock, it is a cold bath, whether the absolute temperature be 60° or 95°.*

In any infectious disease there is the obvious indication of removing waste-products.

4. *The cold bath—as just defined—removes comparatively little excrementitious matter from the body, it checks any existing tendency to sweating, and throws the blood inward to organs already infiltrated or irritated by toxic principles.* It is claimed that the baths increase the renal elimination. Many of the case-reports brought forward to support this theory simply cite the quantity of urine passed. Comparing this quantity with the amount of fluid nourishment and water drunk, and considering the possibility of still further absorption of water through the skin, it is obvious that three alternatives confront the patient—diarrhœa, excessive diuresis, or dropsy.

5. *The fact that much urine is passed, or even that urinary solids are increased during treatment by immersion, does not show that the kidneys are acting in a more healthful manner, but that they are being subjected to greater strain.*

6. *The immediate effect of cool immersion is to cause congestion of the internal organs, adding fuel to the inflammatory foci and embarrassing the heart, lungs, liver, spleen, and kidneys, whose functions are already severely taxed by disease.*

7. *The fact that the patient leaves the bath with blue lips and chattering teeth is not simply an æsthetic objection, as has been declared.*

If the immersion-treatment is not markedly and directly antipyretic—and the strict disciples of Brand say that it is not—and since it is not an aid to elimination—even granting that elimination is not interfered with—what is its *modus operandi?* Dr. Baruch, one of the ablest advocates of the method, ascribes to it tonic properties, explicable on the theory of increased phagocytosis. Now, the undoubted benefits of cold bathing for persons of debilitated but not diseased constitutions may well be explained on the theory that the functions of the leucocytes are stimulated; but the writer's prejudice against the immersion-treatment of typhoid fever rests largely on a study of the effects of bathing and swimming on healthy or comparatively healthy persons. The temperature of still lake-water, near shore, whatever the size of the lake—excepting a few very deep and cold lakes fed by subaquatic springs—is about the same, and on sunny summer days varies from 70° to 85°. The writer has studied for three summers—not to mention less systematic observations for a much longer period—the effects of swimming on some two hundred persons, mostly boys of about fourteen, but including a number of girls and women, and of all ages from four to seventy. It should be said that the observations were direct and not statistical, a bathing-suit not affording the conveniences for taking accurate notes. As the conclusions reached have a direct bearing on the subject of the paper, they are numbered consecutively with the other propositions submitted.

8. *Except for menstruation and previous lack of physical training, sex has no modifying influence on the effects of bathing.*

9. *Other things being equal, young children seem to endure bathing better than older people, probably because their circulation is more rapid and because they usually swim in shallower and warmer water.*

10. *When air and water are warm, persons of average vigor can safely bathe twice daily. More frequent baths produce depression in all but the most robust.*

11. *Under the most favorable circumstances the bath should not be prolonged beyond half an hour, and for most persons fifteen minutes is the proper limit.*

12. *Drying and dressing should never be postponed after subjective or objective symptoms of chill present themselves.*

I have often noticed boys with livid or almost white lips who persisted in the declaration that they were not cold. I was compelled to doubt their truthfulness, especially as indifference to this rule resulted in diminished strength, in lagging at games and other athletic exercise, and in loss of appetite, and predisposition to colds, transient dyspepsia, etc.

Can we expect that the typhoid-fever patient will receive all the benefit from immersion that a healthy person gains and be immune from the possible disadvantages? The advocates of immersion practically answer this question in the affirmative. The genuine Brand bath employs water of about the same temperature as that of the surface of a lake on a warm summer day. As often—perhaps usually—practised, the temperature is about what the swimmer finds on a cool day or after the water has been stirred up by a storm. The period of immersion is practically the same as that assigned for lake-bathing under favorable circumstances, and twice that allowable for bathing in cool water. Thus we may say that:

13. *The average immersion-bath is as cold and as long-continued and is repeated from two to four times as often as that which a healthy swimmer of average vigor can endure without evident depression.*

14. *The typhoid patient has not the benefit of exercise during or after the bath, nor of increased circulation and respiration inevitable in the effort to keep the nose above the surface of the water.*

15. *If the typhoid patient is to be immersed at all, he must be lifted to and from the tub with the greatest care; he must be thoroughly dried and warmed with towels, and the same water must not be used for several patients.*

How is the typhoid patient protected from the ill effects which would be inevitable in a healthy person from bathing similar in temperature, duration, and lack of exercise? Speaking from purely physical consideration of the subject, we may say that the elevated temperature of the disease protects him; but—

16. *There seems to be something more than mere abstraction of heat-units in the depression subsequent to bathing.*

Aside from the nervous and semi-hysterical shock which girls and even men unaccustomed to swimming experience from entering deep water, it is noticed that young children bathing in the shallowest and warmest water, and who present no evidence of chilliness, are gradually weakened by too long and too frequent bathing. Much of the so-called malaria after vacations is due to what some physician has termed water-soaking. The word is not scientific, and I cannot furnish a rational explanation,

but the fact of depression following a course of bathing without obvious chilling is well established.

After all *à priori* arguments, there remains to be considered the magnificent accumulation of statistics in favor of the immersion-treatment of typhoid. However, it must be recognized that, while figures do not lie, they may be as misleading as certain persons who are literally truthful. It is easy enough to complete a certain kind of statistics to show that tobacco, alcohol, and narcotics in general conduce to longevity; every new drug, however worthless it may prove to be, comes to us supported by unimpeachable authority and unanswerable case-reports. Anyone who has tried to generalize from his own case-records, without attempting to prove any particular theory, knows how often he is puzzled as to the classification of individual cases, and can realize how easily such cases may be made to support either side of an argument. Typhoid is the only common specific disease that lies within my field of practice, and it is unpleasant to feel that I am in opposition to the best and most modern authorities; yet I am comforted by the outcome of similar conservatism in regard to the therapeutic properties of testicle-juice and tuberculin. It is not possible at the present time to refute the case-reports of hospital attendants nor to show that the "post hoc, propter hoc," fallacy has been committed. Yet the following considerations must be borne in mind:

17. *In comparing death-rates the advocates of immersion very properly exclude fulminating and neglected cases from their own tables, but ignore the fact that just such cases swell the general mortality.*

18. *The average death-rate of properly treated typhoid cases according to any of the older methods is not so high as 20 or 30 per cent., as the immersionists sometimes declare.*

19. *Many, if not the majority, of ward-patients are stimulated by the ordinary comforts of cleanliness, warmth and even temperature, regular and comparatively wholesome feeding, etc.; whereas patients in private practice are accustomed to and require a higher scale of physical comfort.*

20. *The advocates of the immersion-treatment include in their statistics many cases which have had but few baths, and which an unbeliever would say recovered in spite of, rather than on account of, immersion.*

21. *Hemorrhage, shock, etc., prevent the carrying out of the immersion-treatment in many instances.*

22. *Actual shock is sometimes observed by the advocates of the immersion-treatment, but is usually relieved by prompt stimulation.*

I have, in another paper, alluded to a patient whose temperature went down nine degrees after a bath. So far as statistics show, this case favors the immersion-treatment, yet a glance at the bedside-record will convey exactly the opposite lesson.

23. *We may well doubt the good faith of some who practise immersion in hospitals, but who do not urge it on their private patients.*

24. *The claim that the immersion-treatment expedites convalescence and leaves the heart without the usual post-typhoid weakness, is denied by many physicians who have had charge of patients after their discharge from hospitals.*

In conclusion, let me say that I am not writing to support a theory, nor to assail the advocates of an opposite theory, but to elicit the truth. I am open to conviction and ready to acknowledge an error.

ON THE VALUE OF THE COMPARATIVE METHOD IN THE STUDY OF PATHOLOGY.[1]

BY ROSWELL PARK, A.M., M.D.,
OF BUFFALO, N. Y.:
PROFESSOR OF SURGERY IN THE UNIVERSITY OF BUFFALO.

(Concluded from page 119.)

AMONG the most remarkable phenomena pertaining to cells is the peculiar tendency to reappearance of traits and qualities peculiar to remote ancestors, and quite out of keeping with cells in their present locations. Sutton divides these into *vestigia*, or those affecting whole organs or races, and *degenerations*, or those affecting general groups of tissues. It is the partial reappearance of traits and qualities peculiar to some remote ancestor which we speak of as vestigia. Among these are most prominent, for example, the congenital malformations of the ear and the appearance of rudimentary or additional auricles. In fact, the whole arrangement of the external ear shows atavism toward the type of the carnivora and herbivora, the rudimentary and now useless muscles pointing clearly to the movable ear of those orders. But the human ear points further back than this, and by its development from the remains of the first branchial cleft points distinctly to fish-ancestors and gill-covers, the auricle being the relic of the operculum. Other relics of the opercula appear in the appendages so well described by Sutton as cervical auricles—*i. e.*, the little tags which make their appearance along the anterior border of the sterno-mastoid. That these are not mere freaks is shown by the fragments of cartilage, muscle-fibres, etc., which they contain. These appendages may be cystic or open, forming diverticula to such an extent that fistulous passages may extend clear through to the pharynx, forming the so-called branchial fistulæ.

But it is rather to another aspect of the embryology of the head and neck, especially in its ontogenetic and surgical relations, that I would like for a few moments to invite your attention. Sutton has shown (*Journ. of Anat. and Phys.*, vol. xviii. p. 28, "A Critical Study of Cranial Morphology") that the bony framework of the skull, morphologically considered, is a mere addition to the original primary cranium, which is in reality represented by

the dura. Very early in embryonic life the dura and the skin are in contact, while the basal and lateral portions of the cranium gradually chondrify, thus separating these two structures. We too often forget that the skin and dura are in contact along the various sutures, often for a year after birth, and that this close relation persists longest in the region of the fontanelles and the torcular. The practical bearing of this is that the formation of an intracranial dermoid, by inclusion within the rapidly growing cranium of a few dermal or epiblastic elements, is not difficult to understand. The pedicle of such a cyst or tumor may easily become surrounded by the rapidly forming new bone, in which case the cyst may be entirely covered, or may be with or without some trifling fibrous connection with the overlying scalp.

But of much more importance than this is the original communication between the primary alimentary canal and the central neural canal. Additional facts proving both the anterior and posterior communication of these original canals have only been recently brought to light, and are of sufficient importance to justify some description in this connection. Some fifteen years ago Owen attempted, unsatisfactorily, to show that the gullet of ancestral vertebrates was continuous with the third ventricle, and that the space from the pineal to the pituitary bodies by way of the infundibulum represented this primary gullet. He had, however, been preceded by Dohrn, who thought that the fourth ventricle marked the place where the œsophagus pierces the nervous ring. It has remained, however, for Gaskell and Sutton to show that the tube which now represents the central nervous system in the invertebrates is really the disused segment of the former primary canal. These two scholars, working independently, have arrived at fundamentally the same results. They have profited by Hertwig's investigations, who has shown that the original pleuro-peritoneal cavity is a derivative of the fundamental alimentary canal, arising as two separate diverticula whose central portions persist as the permanent alimentary canal, while the lateral portions coalesce to form a common pleuro-peritoneal chamber. This fact is of no small importance, both from the embryological and the pathological standpoints, since it shows how the cells lining the peritoneum are really of original hypoblastic origin, and that the pleuro-peritoneal cavity is represented in the invertebrates in the so-called gastrula-stage of inversion of the exterior surface.

In the very young embryo we find a fundamental U-shaped tube, from whose anterior branch is developed the alimentary canal, and from whose posterior branch, representing the notochord with its central neural canal, are formed the brain and spinal cord. This tube is lined by a continuous layer of columnar epithelium, and terminates at the cephalic end by a cul-de-sac. The anterior branch is widely open to the yolk-sac, and this becomes connected with the exterior by an epiblastic involution which opens up the cephalic end of the now primary gut; while at the same time a diverticulum, the so-called pouch of Rathke, makes its way in the direction of the cephalic end of the other branch of the original tube, uniting with it, in fact, by an analogous diverticulum produced from the other side, to which I shall recur in a minute. Again, at the caudal extremity there is another involution of the surface, where an opening is established. All that remains of the anterior branch of the primary U-shaped tube between this division and the posterior branch, known as the post-anal gut, is represented in the adult by Luschka's or the coccygeal gland. Occupying the flexure of the tubes is a chain of sympathetic ganglia with branches to each section. The anterior branches ramify in the walls of the bowel and develop intrinsic ganglia and plexuses, with which the names of Auerbach and Meissner are closely associated; while those going to the posterior disappear in its substance, join with groups of nerve-cells developed in the thickness of its walls, and form the gray matter of the spinal cord. In this way certain nerves persist and bring these two systems into close relationship; these are known as the splanchnic. Thus it will be seen that in the dorsal section development is in the direction of nerve-cells, while in the ventral section development is rather into muscle-cells, the two being associated by the splanchnic nerves. The epithelium lining the posterior tube fails to develop; that lining the anterior becomes highly specialized for digestive purposes. Although it may disillusionize some of us, it is, nevertheless, to be stoutly maintained that the canal of the central nervous system is really of intestinal origin, as shown by their original continuity, their similarity in fashion of development, their correspondence in point of time, their close inter-relation through the splanchnic nerves, and by the association of numerous malformations of the central canal of the cord with deformities of the alimentary canal.

What, now, is to be said of the anterior communication of these canals? If one will take the trouble to dissect carefully the macerated sphenoid bone of a six or seven months' fœtus (or younger), he will find it to contain much fibrous tissue, in the midst of which he will detect a small canal that may be entered, sometimes even in the fœtus at birth, by a small probe introduced in a minute recess of the mucous membrane exactly in the middle line of the nasopharynx, close up to the base of the skull. This pocket, often half an inch deep, is known as the bursa pharyngea, and may often be seen in the adult. It marks the pharyn-

geal termination of what is known as the craniopharyngeal canal. It would be noticed much oftener were it not surrounded by a collar of lymphoid tissue, known as the pharyngeal tonsil, corresponding to the collections of lymphoid tissue which mark the site of other obsolete canals. The internal opening of this canal is to be found in the floor of the sella turcica. This is the remains of the diverticulum already alluded to, which has made its way from the cavity produced by the infolding of the integument at the cephalic end of the anterior branch of the original U-shaped tube.

The remains of the other diverticulum, extending anteriorly from the upper end of the posterior branch, are to be seen in the fourth and third ventricles and their communication with the infundibulum. Here, again, the relation of the pituitary body and the so-called pineal gland to this anterior neurenteric communication is most interesting and most important. The structure of the pituitary body is so often likened to that of the thyroid, the thymus, the adrenals, etc., which are all of obscure origin, that anything shedding light in this direction is of great interest. According to this view we must, then, regard the pituitary body as the intracranial lymphoid tissue, which again marks the site of this obsolete canal. I think the investigations of Beard, Gaskell, and Sutton may now be regarded as clearly establishing this fact. Wiedersheim also regards what he calls the pineo-pituitary tract as the primitive mouth-part, archæostoma, or gullet of the ancestors of the vertebrates, the present mouth (neostoma) being an ingrowth, as indicated, between two branchial arches. If in this way the pituitary body can be shown to have, embryologically at least, a more intimate relation with the alimentary system, it may help to shed light where it is much needed—upon the obscure etiology of such a disease as acromegaly.

This brings up also the proper position of the pineal gland, so-called. Within a few years we have been taught that this is the remains of the pineal eye, or that it is to be classed as an original and perhaps rudimentary sense-organ. But later researches have failed to confirm this theory, since it has nowhere been found functional. I may quote a statement from Prof. Woods Hutchinson, nephew of Jonathan Hutchinson, who states in a letter to me:

"I have carefully compared all the plates and representations of this organ and its sections which I could procure, with the result of a decided conviction that all that can be said of this body is that it was an epithelium-lined cavity at some time, communicating both with the surface and the ventricular cavity of the brain; and it has as much the appearance of having been mouth and gullet as eye-bulb and optic nerve. I have also consulted several morphologists upon the question, and they tell me that all one can definitely say is that it is the degenerated remains of an epithelial (cerebral) outgrowth of some description."

(See also editorial by him in THE MEDICAL NEWS, June 6, 1895: "Is the Brain an Appendage of the Alimentary Canal?")

If this view be accepted, a large class of hitherto mysterious processes and lesions is more susceptible of explanation than by any other theory yet devised.

Accepting, then, the pineo-pituitary-infundibular passageway as marking the site of the original anterior communication, let me again refer to the posterior communication between the neural and enteric canals, this being the lower part of the original U-shaped tube already alluded to. Here, first of all, is Luschka's gland, a mass of lymphoid tissue marking the site of the obliterated passage. The first to appreciate the true character of congenital coccygeal tumors and to associate them with this canal was Middledorpf[1]. These tumors, like all others developing from this lymphoid tissue, always assume dermoid characteristics, and are for the most part situated between the rectum and the cæcum, though when large they may make their way into various parts of the pelvis. (For example, I have lately successfully removed one from a man of fifty, which had pushed its way from within entirely out of the pelvis and had raised a conspicuous and tender prominence in the gluteal region, which almost completely disabled him. After removal it weighed four pounds.) These dermoids intrude themselves in all directions within the pelvis, and curious instances are recorded, many of them in the *London Pathological Transactions*. To the same general class belong also most of the congenital coccygeal tumors which figure in the monographs of Calbet[2] and others.

Per contra, equally well-marked dermoid tumors are met with in the original location of the infundibulum, especially in connection with the pituitary body. They have been described also as growing from the body of the sphenoid and projecting into the orbit or in other directions.[3] And the same is true also of the lower end of the infundibular canal, dermoid tumors being often found in the vault of the pharynx; while adenomatous enlargement of the pharyngeal tonsil is extremely common, particularly in children.

The origin of dermoid tumors from this original lymphoid tissue in the neighborhood of obsolete canals has equal interest and importance in considering the embryology of the thyroid body, which arises as a separate diverticulum from the anterior

[1] Virch. Arch., vol. ci. p. 37.

[2] Contribution a l'Etude des Tumeurs Congénitales de la Region Sacro-coccigienne, Paris, 1893.

[3] Lawson: Path. Soc. Trans., vol. xxxv. p. 379.

wall of the pharynx or floor of the mouth. In all but the lowest forms of vertebrates this diverticulum becomes completely shut off, and the duct leading to the developing thyroid is early rendered obsolete. In man it persists for a short time in the embryo, and is known as the thyro-hyoid duct, first described by His. By the time the hyoid bone has developed this duct has divided, that portion above becoming the lingual duct, that below remaining as the thyroid duct. This latter is often known as the *processus pyramidalis*, since it usually contains muscle-tissue, and has been described in most text-books of anatomy as the levator of the thyroid. When either of these ducts persists the fact is usually known by continuous shedding of epithelium, and perhaps discharge of sebaceous material. At times the ducts dilate into cysts of considerable size. Thus, I have recently had occasion to exsect such a cyst, the size of a hen's egg, from the floor of the mouth and base of the tongue in a young woman. The thyro-lingual duct originally opened upon the tongue at the point where now we have the lymphoid tissue known as the lingual tonsil. Along this location dermoids often develop, which may be central, unilateral, or bilateral, the central dermoids appearing, for the most part, as retention-cysts in the original thyro-lingual canal. It is worth while to remind you also that in case of epithelioma developing in this neighborhood the malignant process may extend rapidly down this canal and produce a perforating ulcer of the tongue—a melancholy instance of which recently occurred in a prominent officer of the army medical corps.

The thyroid duct should also completely disappear, but may persist, either as a duct extending from the thyroid isthmus to the hyoid bone, usually surrounded by muscle-tissue; or as a canal obliterated in the main, but presenting interrupted dilated portions—*i. e.*, a series of cysts; or, lastly, it may be represented by a series of detached bodies, known ordinarily as accessory thyroids. These supernumerary thyroids are to be regarded always as the persistent remains of this original passage, and not in any other light. Both in the persistent or obliterated track, as well as in the thyroid body itself, cysts are most prone to develop, varying much in size, contents, rapidity of growth, etc. Some are multiple; some are single. The most interesting of them all are the dermoids, which are intimately related in structure to those dermoids found in connection with Luschka's gland and the post-anal gut. Fifty years ago von Ammon dealt with these in his remarkable treatise, and they have been frequently met with since then.

Another of the obsolete canals in the body to which too little attention is generally paid is that known as the vitello-intestinal duct, which originally connected the yolk-sac outside the embryo with the developing alimentary canal. This occasionally fails to become obliterated as it should, and may then present either as a protruding vascular tumor at the umbilicus or as a form of umbilical and fecal fistula, or as a dermoid located within the abdominal parietes. (I have had occasion within a short time to operate on a young man who had nearly all his life had a discharging sinus from the umbilicus, into which a probe would pass three or four inches. Upon abdominal section, I found a minute external opening connecting interiorly with a good-sized cavity lined with epithelium, and this, again, connecting with the small intestine by a trifling orifice. The extirpation of the sac and the sinus with intestinal suture was sufficient to obviate completely the difficulty.)

Another form of umbilical fistula is that represented by pervious urachus. This is so commonly dealt with in text-books that, beyond reminding one that the urachus may be in part obliterated but presenting cystic dilatation in some portion, or that just at the outlet it may be connected with a dermoid growth, I will not detain you with its consideration.

The subject of branchial fistulæ is also one of great interest. This is now quite thoroughly dealt with in works now before the profession, and need call for but little attention here. Their study and recognition are entirely matters of the present century, for the most part of the latter portion. Heusinger made a most marked advance when, in 1864, he analyzed forty-six examples of the malformation (*Virch. Arch.*, vol. xxix.). These branchial fistulæ are the persistent remains of the original branchial or gullet clefts, and at present persist only among the fishes. They should all be closed long before birth, save only the first, which forms the tympanic or Eustachian canal. When the second remains open, in whole or part, it opens usually between the angle of the jaw and the sterno-mastoid muscle. When the third fails to close, the opening is situated opposite the thyro-hyoid space, close to the sterno-mastoid. The fourth, when open, presents just above the sterno-clavicular junction. This is the more commonly persistent of the three. Internally or within the pharynx these clefts present in the following locations: The second in Rosenmuller's recess, between it and the tonsil; the third and fourth, into the blind canal, called by His the precervical sinus, these being intimately related with the development of the thymus body. Thus the thymus is tissue intimately related to the lymphoid which marks all obsolete passages, the tonsils themselves bearing a very close relation to the second cleft.

These branchial clefts present either as complete fistulæ, external culs-de-sac, internal ditto, or cystic dilatation of intermediate portions, both orifices

being closed. It is now well established that certain pharyngeal diverticula are due to internal blind openings of these clefts. Watson (*Journ. of Anat. and Phys.*, vol. ix. p. 134) has described the most remarkable case on record of this general character. Sutton, moreover, has already made statement that certain of the so-called sebaceous cysts occasionally met with beneath the deep cervical fascia are in reality dermoids arising in persistent branchial remains, and, consequently, analogous to dermoids of the tongue originating in the lingual canal. Harrison Allen has recently thrown much light upon the little masses of glandular or adenoid tissue situated in the fauces, by showing that they are the relics of the second branchial clefts, the pharyngeal tonsil, of course, marking the lower opening of the infundibulum. It might be well just here to digress for an instant to remark that lymphoid tissue thus located, no matter where, about the body, is always peculiarly prone to infection like other degenerated tissues, and that when infected it succumbs most easily to disease. This is conspicuous about the appendix, for instance, where it so frequently leads to disaster. It is commonly seen, moreover, about the tonsils and other tissues scattered about the pharynx.

I should add further in this connection that the congenital fistulæ occasionally met with in the middle line of the neck are not to be confounded with branchial fistulæ, but are to be referred to persistent remains of the thyro-lingual or thyro-hyoid ducts.

There is always a tendency when we start at the top of that which has been growing to credit the growth with the tendency to rise. To judge fairly, however, one should start at the bottom, and begin by ascertaining how many other members of the group studied have taken other directions and partly or completely failed. The higher the place of an organism in the vegetable or animal scale the more restricted are the limits within which it is able to vary or to progress. As Coste has observed, few things are more instructive than the phenomena of blind alleys in evolution—that is, the evolution of certain growths along lines which stop abruptly, as if capacity for further development were wanting. Coste has followed out this line of reasoning in the vegetable kingdom in a very interesting way, but one which takes us too far from our present subject. (*New Science Review*, "Evolution and Teleology," July, 1895, p. 65.)

It often happens that the foliage proceeding from adventitious buds is very different from that of the rest of the plant. This is in accord with the theory of reversion, and these analogies are most common in the lower orders. Bud-formation is chiefly determined by nutritional conditions, and implies always relative excess. That is, the forces resulting in growth are in excess of the forces antagonistic to it.

Even the dreaded tumors may be viewed from the same standpoint as a reversionary process. When animals are hard pressed for existence they appear to become more prolific. This is notably true in the human race, which seems to have the highest degree of fertility where the struggle for existence is the most arduous. In the case of the infectious granulomata, for instance, cells multiply in soil already impoverished, but show inherited weakness by their incapacity for prolonged existence. In the presence of a specific virus of any kind these tissue-cells show a disposition "to be fruitful and multiply," as Hutchinson says, "no matter what comes of it."

Thus reversion to earlier type in the avian and reptilian stage is remarkably shown in our liver-cells, where the tendency so often is to the elimination of nitrogenous materials in the form of uric acid rather than of urea. The wide bearing of this reversionary tendency upon the very common malady known comprehensively as Bright's disease is apparent if we remember that the primary arterial lesions are, in all probability, due to the circulation in the blood of an uric-acid irritant, giving rise to the so-called arterio-capillary fibrosis. It is well known that among bipeds uric acid is eliminated by liver-cells without having undergone metamorphosis into urea, the urine of birds being solid instead of containing excretory material in watery solution. In fact, as Garrod says, "Our gouty patients are a sort of birds."

Certain nervous diseases possess characteristics justifying our regarding them as reversions to certain forms of activity normal in more or less remote ancestors. In the case of goitre, this has been practically established. It is curious, by the way, to note that goitre affects the lower animals almost always in those parts of the world where it is common in man. Horses are most liable; then dogs, calves, and lambs. Cows and sheep are not so liable. Cystic goitre in various small animals, like squirrels, has also been reported.

But perhaps nowhere does reversion or atavism manifest itself more conspicuously or unmistakably than in the mutual convertibility of skin and mucous membrane. The former, being subjected to more modifying influences, of course undergoes more frequent changes. Thus, it furnishes in various animals hair, feathers, bristles, quills, horns, scales, etc.; and in the lower animals it furnishes glands which secrete mucus, milk, poisonous fluids, or fluids loaded with calcium salts, by whose deposition shells or even pearls are formed. Moreover, these characteristics are maintained in dermoid cysts found in these same animals. Thus in sheep they contain wool; in cats, hair; in pigs, bristles; and in birds, feathers. It is well known, moreover, that gray hairs are occasionally met with among the very young. So, also, in young subjects dermoids occasionally, but rarely, contain gray hair.

The mucous membrane has been called "the internal skin." In some respects this is more than a mere happy expression, because from this membrane may be developed many of those structures which we find in or upon the skin. Its most distinctive feature is its epithelial covering, which is ordinarily hypoblastic, but which blends in the buccal cavity, for example, with the infolding of epiblastic epithelium, whose papillæ calcify and form teeth, and from which in many animals there develop hairy patches upon the inside of the cheek. Moreover, sebaceous glands are not confined to the skin, but are large and frequent; *e. g.*, in the mucous membrane of the nymphæ. *Per contra*, mucous glands occur in the skin of reptiles, worms, and fishes. Among the shell-fish the external glands secrete or produce the shell, while in reptiles and birds it is the glands in the oviduct which take on this shell-forming function, producing it rather for the egg than for the parent individual. We also know that calcareous formations are common in the human prostate as well as elsewhere. But it is not alone in those places where the epiblast and the hypoblast meet that such epidermal products are found. If skin and mucosa be really interconvertible, why should we not look for hair in the alimentary canal? And if we do, we are not disappointed, because at least in certain birds there is a curious pyloric plug—filter, as it were—composed of hair. Garrod has shed much light upon the frequency of hairs growing from the mucous membrane. (*Collected Works*, p. 334.)

It is often seen that those structures ordinarily regarded as dermal are not at all necessarily so. Thus, the thick part lining the bird's gizzard is composed of epidermal cells, while pigment occurs in the mouths of many animals and in the vaginæ of many others. Calcareous deposits occur in the human prostate, in the oviducts of birds, reptiles, and monetremes, and upon the outside of many of the invertebrates. Hair is seen in the stomachs of certain birds, upon the eyes and in the mouths of many animals; mucous glands inside the alimentary canal of man, upon the skin of reptiles, fishes, and worms; sebaceous glands ordinarily upon the dermal covering, but as well in the nymphæ of the human female. In the South are met certain blue-gum negroes, so-called because of the excessive deposition of pigment about the gum and palate. Here, too, we have a reversionary or atavistic manifestation.

Thus, again, it will be seen that there is no one characteristic by which we can make a primary distinction between the skin and mucous membrane. Moreover, the old statement that the former is epiblastic and the latter hypoblastic will scarcely suffice, for certainly the conjunctival sac is a typical mucous surface, yet equally certainly it is derived from the epiblast, of which it occasionally shows some more active relic. The atavistic tendency is shown even further in the conversion that can be actually seen upon the surface of a long-extruded hemorrhoid, where the columnar epithelium of the hypoblast becomes metamorphosed into the scaly epithelium of the epiblast.

From all of which follows the corollary which Sutton has been quick to formulate, that a cyst lined with mucous membrane should be as readily admitted into the category of dermoids as one lined with skin, providing that either arise in situations where skin and mucous membrane do not ordinarily occur.

Let me next call your attention to the significance of polymastia, the so-called supernumerary and paramammary breasts, and to the allied topic of gynecomastia. Aristotle refers to the yield of milk from male goats, and Blumenbach described a case in which the animal had to be milked every other day for a year. Isidore St. Hilaire kept for many years in the Jardin des Plantes a large uddered he-goat that freely gave milk. It is well known also that among the Pomeranians, and certain other people as well, the male breast yields milk very often.

Laycock, some years ago, made a suggestion that mammary-gland tissue may make its appearance upon almost any part of the human body. It is known to occur also in ovarian dermoids, while the occurrence of supernumerary breasts in such situations as the perineum would corroborate this statement, as well as the view that the mammæ are essentially nothing but specialized sebaceous glands that may be met, in normal or aberrant condition, in any portion of the skin. It is well known also that nipple-like processes are attached to the skin in many places, and that mammary tissue is found in locations unprovided with ducts. It is likely that this specialized tendency of sebaceous gland-tissue will account for the crops of furuncles which appear occasionally in the axillæ, especially in women, and most commonly about the menstrual period. This is certainly a manifestation of atavism, the atavistic side of it being shown by the abnormal presence of this tissue, while the furunculosis is, of course, to be explained entirely by accidental infection. In animals axillary mammæ are most exceptional, but they are met with in the fruit-bats and in the flying lemur. Schultze finds that in multimastic animals the first mammary rudiment presents as a linear thickening of the epidermis, along a line nearer the dorsal than the ventral surface, in which at various spots lenticular thickenings occur, between which the connecting strands disappear, and from which

[1] There is at least a superstition—how well founded I cannot say—that the bite of a "blue-gum nigger" is peculiarly infectious. This I learn from gentlemen who have practised in the South.

the individual glands are later developed. The domestic cow has normally four well-developed and often two rudimentary teats. The latter may be occasionally so well developed as to yield milk. Other anomalies met with in the cow are disproportion in size of those normally present, or the placing of one or several supernumerary teats always behind the normal ones. In sheep the supernumerary teats are always placed in front of the normal ones. It occurs occasionally in the human species that a supernumerary nipple is placed in or near the middle line, either upon the thorax or the abdomen. This must be regarded as a distinct reversion to the marsupial type, since in the marsupial pouch three nipples are scattered along this line. Williams has done a great service by calling attention especially to the trefoil arrangement of the mammary gland in the human female, and to the important clinical fact that this arrangement is often overlooked by operators, who fail to dissect out during operations for cancer the ultimate portions of this trefoil arrangement, in which later recurrence may consequently more easily occur. The trefoil arrangement is practically a tendency to return to the polymastia of earlier days, and may be regarded as an atavistic polymastia.

But, passing from this interesting topic to a few practical illustrations of the bearing of evolution upon pathology, I must remind you that we often lose sight of the fact that there are changes in the human organism not so very much less striking than those which convert the tadpole into the frog. Aside from those to which I have already called your attention, we see instances in the teeth, the thymus, the breast, the uterus, the skeleton, etc., most of which indicate the possibilities of tissues remaining unchanged for long periods, and then taking on new phases of growth by reversion to a state of embryonic activity. While in the ordinary course of organic evolution cells develop in regular and orderly manner in accordance with inherited tendencies, occasionally they arise at places where they have no business, or at inappropriate times, and then grow to an extent at variance with normal formation. In this way are produced embryonic monsters, and malformations as well as various neoplasms.

Wisdom-teeth are to be regarded as reversions to a form of ancestors having a jaw long enough to contain more teeth, at least five or six molars. The extra incisors which appear at the edges of the premaxillary bone in extreme cases of harelip are also atavistic in character.

The well-known characteristic of so-called Pott's fracture of the fibula has been shown to be largely due to the fact that this bone is a rapidly disappearing relic, which, in fact, in many of the lower animals has already completely disappeared. In the human embryo at the third month the two bones of the leg are equal in size.

Of all the forms of club-foot, that known as equinovarus is the most common. It is the normal position of the foot in the embryo up to the seventh month, and in many of the quadrumana throughout their lives.

The acneal pustules which appear upon the face of adolescents at the period of puberty are, in effect, only atrophied hair-follicles or sebaceous glands endeavoring to produce the hirsute covering of our former ancestry.

It is of interest, also, to know that eczema is by no means confined to the human skin, but that it is one of the common heritages of nearly all living surface-tissues. Woods Hutchinson has shown that its oldest analogue is the exudation of gummy and resinous fluids upon the stems or leaves of plants and trees for the healing of wounds, and protection against fungi and entanglement of insect enemies. Quite analogous also is the outpour of protoplasm from the surface of an amœba, by which it encloses or attaches foreign bodies coming in contact with it. Among certain plants we find a disease which may be regarded as vegetable eczema, particularly in the so-called "apple-scab," which is caused by a distinct fungus (*fusicladium dendriticon*). In the course of this vegetable disease a distinct papular stage is seen, to be followed by an equally distinct horny stage, in which a layer of cork-like tissue is formed. Among tubers a similar disease known as the "potato-scab" is quite common. Among domestic animals mange in dogs, grease in horses, and foot-and-mouth disease in cattle are almost identical with eczema in the human subject, the irritant, however, being a parasite.

Moreover, as Hutchinson has shown, the preference which eczema seems to manifest for flexor surfaces, and especially flexures, is to be explained upon the principle that it is a dermatitis, and naturally occurs where skin is thinner and more delicate, while the irritating effect of perspiration, dust, heat, friction, etc., is more marked in these localities.

But all these facts to which I have called your attention to-night are more or less isolated instances from which great and important truths are yet to be deduced by those who have knowledge comprehensive enough to utilize them. Unfortunately, these men are as yet rare; and one remedy for this condition of affairs which I place before you as deserving of most careful consideration is the formation of a society in which should meet on common ground botanists, agriculturists, vegetable pathologists, biologists, zoölogists, veterinarians, and human pathologists, where all may exchange ideas, and where each may gain by contact with the others that which will add vastly to his own information

and usefulness. Take the case even of the veterinarians, who practise earnestly and zealously and more and more intelligently in a field which, as one might say, is topographically next to ours. How much they know which might be of value to us, and how much we know which they could apply to the greatest possible advantage in their own work, did they but share the knowledge. It seems to me that the formation of some such society for the interchange of knowledge would be of the greatest imaginable help in the direction indicated.

The other essential, as it seems to me, is a carefully prepared work upon comparative pathology, in which should be recorded, collated, and carefully edited the various facts known to the classes of students just enumerated. Such a work must necessarily be of composite character, since probably no man living knows enough in all these various branches to justify his attempting it as an individual task. Even the selection of an editor for such a work would be a difficult task, and would be a high compliment to the man chosen. In the preparation of a book should be enlisted men like Hertig, who writes most entertainingly of the diseases of trees, and men of his stamp, who concern themselves mainly with the vegetable world. Others, again, like Metschnikoff, who have had a training as zoölogists, but who have the deeper insight which permits of the application of their knowledge to the explanation of the problems of humun pathology, should also be enlisted in this great cause. The ablest veterinarians of the world, and those who concern themselves with such problems, for instance, as are presented in this country to the Bureau of Animal Industry, should also contribute; and, finally, their labors and results should be carefully collated and arranged alongside of the facts presented in our ordinary works on general pathology, and this last by an ideal editor, who should combine vast stores of general information with the knowledge of that which would enable this storehouse of facts to be made available and applicable in the recognition and treatment of diseases in the human race. Thus, even the agricultural chemist, the botanist, and the naturalist might combine to produce a work whose value should so far exceed that of any single work now before our profession, as do our present books those published a hundred years ago upon the same subject.

This, then, is my plea to you in closing, that men in various branches of scientific work should get together and make common stock of their knowledge, and that the results of their investigations be presented to the scientific world in some such way as that indicated. There exist to-day no works in any language on comparative pathology. The ideal work to which my longing points would require two, three, or even more volumes,[1] and should be epitomized in condensed form, which could be placed in the hands of every second-year student, and upon which he should be fed, as it were, from the beginning of his second year until after his graduation, when the larger one should be in his hands until he has familiarized himself with its contents. When this happy condition of affairs is brought about, we shall have men in our profession who are liberally educated, shining in the light of a knowledge which, after all, would be focussed upon the problems of disease in man; and, then, and I fear not until then, can medicine claim the title and privilege of being really liberal.

> There are great truths that pitch their shining tents
> Outside our walls, and though but dimly seen
> In the gray dawn, they will be manifest
> When the light widens into perfect day.
>
> LONGFELLOW (*Michael Angelo*).

IN WHAT MANNER CAN ULCERATIONS OF THE NASAL SEPTUM FOLLOWING OPERATION AND IN ATROPHIC RHINITIS BE HEALED TO SECURE AN EVEN AND MOIST SURFACE?[2]

BY CLARENCE C. RICE, M.D.,
OF NEW YORK;
PROFESSOR OF DISEASES OF THE NOSE AND THROAT, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE consideration of such a topic as this may, to the casual observer, seem unimportant. At first thought it would appear sufficient to be able to heal ulcerations on the nasal partition in any manner, but we all know how important it is to repair nasal ulcerations and obtain a cicatricial surface which will not accumulate secretions. Retained nasal secretions upon the septum, besides being a cause of obstruction and general annoyance, eventually lead to secondary ulceration.

This paper will necessarily be short, since the treatment which will be advocated is very simple and can be quickly stated. We may, for convenience, classify ulcerations of the nasal septum into two large divisions—first, those resulting from operations, and, second, those appearing as a stage of some one of the several varieties of inflammation of the nasal passages. Perhaps it would be wise to exclude the ulcerative stages of syphilis, lupus, and tuberculosis, because the treatment of these is largely constitutional, although in these diseases ulcerations require careful local attention. First, let us speak of ulcerations on the nasal septum caused by operative procedure. It would be well to say at the outset that the more nearly normal

[1] A new work of promising character in this direction is announced by Lubarsch and Ostertag (*Allg. Path. und Path. Anat. des Menschen und der Thiere.*).

[2] Read before the Laryngological Section, New York Academy of Medicine, January 22, 1896.

from the standpoint of healthfulness the nasal passages are, the quicker will the nasal tissues recover after operation. But little need be said in regard to the healing of ulcerations on the *turbinated* side of the nose, for cleanliness, disinfection, and perhaps occasional stimulation will do all that is necessary in a healthy patient. Ulcerations on the septum produced by operations will heal much more quickly and with a much fresher cicatrix in moist hypertrophic conditions than in atrophic disorders. The difficulty lies chiefly in the treatment of ulcerations where the septum is dry, atrophied, and presents more or less irregularity of surface. We note, too, a difference in the behavior of ulcerations following the different methods which are employed to reduce the thickness of the nasal septum. It has long seemed to me that the use of the galvano-cautery upon the nasal partition should not be encouraged. I am not in the habit of using it except over very limited surfaces, as, for instance, upon a small projection of cartilage, too small to require the use of saw or trephine. We occasionally find, too, an œdematous, boggy condition of the soft tissues of the septum where a very limited application of the galvano-cautery may be employed instead of the mineral acids. The use of the galvano-cautery over an extensive surface, to remove deviations of the septum or ecchondroses, as a whole, should be deprecated, because it seems to reduce the vitality of the septum very much, and ulcerations so produced are difficult to heal in a way to secure a moist cicatrix. Tissues are removed much more scientifically by some method of excision. We may be excused for briefly mentioning what we believe to be the best way of treating ulcerations after operation to avoid sepsis. We believe that it will be found very rarely necessary to introduce any plug or tampon in the nostrils to arrest hemorrhage. Bleeding almost always ceases spontaneously. I make it my routine practice to have the patient blow the nose very thoroughly after the bleeding has nearly stopped, in order to remove any small pieces of tissue or any foreign body, and then cover the wound with boric acid and compound stearate of zinc. It is not well to wash out the nostrils by post-nasal irrigation until the second or possibly the third day after the cutting. In my experience danger of sepsis is usually past by that time.

Now as to the best method of treating operative ulcerations during the first week. I believe there may be honest differences of opinion entertained. I instruct patients to return the second or third day after operation, but occasionally, when they have not called for a week or ten days, I have been surprised to see how well the wound has progressed in healing, and sometimes without even antiseptic washing. I know that the behavior of the wound depends largely upon the general condition of the nose. Such wounds would not progress favorably without proper cleansing in atrophic cases. In such conditions we cannot do less than employ post-nasal irrigation and general oiling of the surfaces, but in comparatively healthy nostrils it is a question whether wounds upon the nasal septum do not progress as favorably if left untouched for at least ten days. Cicatrization necessarily takes place beneath the protection of the scab and the overlying secretions which catch upon it. If we could wash off all dirt and dust and overlying secretions and leave the thin scab alone over the ulceration, probably the best course would be followed; but this is a difficult thing to do, and the constant rubbing off of the scab, and the uncovering of the wound produce an irritable ulcer, which repairs itself with tissue further removed from a healthy structure than when the ulcerations are left untreated or washed in the simplest manner. If we could treat ulcerations on the nasal septum as we do those on the surface of the body, by the protection of antiseptic coverings, we should probably secure a moist, even surface not unlike the surrounding healthy mucous membrane; but in the nose it is impossible.

Different methods must necessarily be employed to fill in an excavated ulceration and bring it flush with the surrounding surface. I believe the tendency of a nasal ulceration to deepen until in some cases there seems to be danger of perforation occurs more frequently after the use of the galvano-cautery than following excision. I presume we all see ulcerations on the nasal septum after operation which need to be treated diligently in order to prevent perforation. Daily application of such stimulants as nitrate of silver, zinc, balsam Peru, or the use of such powders as aristol and iodol will be found necessary to force the ulcerated surface to granulate. On the other hand, we sometimes, in a narrow nostril, where we are anxious to obtain all the breathing-space possible, are annoyed by the tendency toward overgranulation, and it becomes necessary to excise granulation-tissue many times before we can secure an even surface.

But the greatest difficulty is not so much in making the surface even as it is in obtaining a cicatrix which is smooth, and, more important still, one which is moist. If we cannot secure this, the benefit derived from the operation which we have undertaken is compromised, and the patient does not obtain the relief which we have promised or which he expected.

I have said before that the difficulty of obtaining a moist cicatrix is greater where the galvano-cautery is used, and I also think that the application of the mineral astringents to ulcerations tends to produce a thicker and dryer cicatrix. I believe that apart from cleansing, ulcerations should be handled as little as possible until the surfaces are even with the

adjacent tissues, and then much can be accomplished by the employment of friction with certain mild disinfectants, in removing the granular surface that is left after the healing of an ulcer, and in making it hard, slippery, and moist.

Now let us speak of the ulcerations occurring in atrophic rhinitis. We meet with all stages of this disease, and perhaps a day does not pass that we do not see numbers of small ulcerations on the cartilaginous septum in children and adults who are suffering from atrophic nasal disorder. These are the patients who are annoyed by the retention of scabby secretions upon the nasal septum and oft-repeated nose-bleeds. Antiseptic irrigation with Seiler's solution or with some stronger disinfectant, and oiling, need to be employed. Great improvement can be secured by these simple measures, but to heal the many small ulcerations and obtain an even, moist surface, more needs to be done. We commonly find the collection of dried secretions just in front of some prominence on the septum, or in the large convexity of a deviated septum. It is superfluous to say that the proper methods should be employed to reduce large prominences and to correct the deep concavities of a nasal partition bent upon itself. It is important even to level down small prominences on the cartilaginous septum in order to prevent the retention of secretions in front of them, even when it is not necessary to obtain greater breathing-space. For many years I was in the habit of coaxing these small ulcerations to heal by the application of the so-called stimulants—nitrate of silver, perhaps, being used more than any other. We know that it is even advocated that, in case an ulceration on the septum refuses to heal, it should be burned by the galvano-cautery, in order to change the character of the inflammation. I do not find, however, that such treatment secures in the cicatrix anything but more or less irregular, granular, and dried surfaces, upon which the secretions collect and become dried crusts.

A good while ago, and I believe at first it was in those cases of epistaxis occurring in young adults, who had small ulcerations upon the cartilaginous nasal septum, with a general unevenness of the surface, the entire nasal passage being in a state of beginning atrophic rhinitis—I found that I obtained better results by *rubbing the ulcerations thoroughly* than by the coaxing treatment of stimulants. I was in the habit of introducing a cotton-carrier, and with a small hard pledget of cotton moistened with listerine I rubbed the several ulcerations rather forcibly and for a few seconds at a time. This at first produced bleeding from the superficial ulcerations, but continuing with the rubbing the bleeding was stopped, and not only the ulceration itself, but the adjacent tissues seemed to take on a healthier condition, which resulted in quick healing. I think latterly I have used borolyptol more than anything else, and with better results, and I am in the habit, so soon as the ulcerations following operative work become even with the surrounding tissues, of, we might say, polishing the surface by antiseptic friction applied every two or three days for two or three weeks. The result has been to secure a whiter cicatrix, and one which is smooth and much more moist than the surface of the usual cicatrix. In atrophic rhinitis small prominences of the septum can be rubbed down in this way alone, and I am certain that superficial bloodvessels which easily and continually bleed can be destroyed in this manner, and the small ulcerations healed with an even, moist surface.

I am not positive that it is necessary to use any special medicament, but believe the best are those represented by such cleansing medicines as listerine and borolyptol. *The friction with moist cotton is the important part of the treatment.* I have found, too, that by this procedure it is possible to exhaust certain forms of nervous irritability of the nostrils. I have employed it lately in a case of nasal hydrorrhœa occurring in a nervous woman, who was very much annoyed by constant fits of sneezing and copious transudation of watery fluids from the nose. Friction on the nasal septum was at first unpleasant, and provoked sneezing and stoppage of the nose; but after it had been continued for a week the nostrils became much more tolerant, and the discharges were very much diminished. I believe it to be possible to destroy the over-sensitiveness of peripheral nervous filaments in this way, and to control many of the annoying vasomotor disturbances which are frequently seen in the nostrils.

The points which I would advance, then, are the following:

1. That ulcerations on the nasal septum produced by operative work repair themselves promptly and with an even, moist cicatrix, just in proportion to the degree of general healthfulness of the nasal mucous membrane which exists; much better in hypertrophic than in atrophic conditions.

2. Ulcerations produced by the galvano-cautery do not heal in so favorable a manner as those caused by excision.

3. In healthy nostrils little beyond antiseptic irrigation should be done in the treatment of operative ulcerations until they are even with the surrounding tissues; then the surface should be rubbed forcibly with an appropriate antiseptic stimulant, such as borolyptol or listerine, until the surface of the cicatrix is smooth and moist.

4. This same frictional treatment should be used to heal the multiple small ulcerations in atrophic rhinitis, and to level and make moist the cartilaginous surface, and so prevent the accumulation of dried secretions.

5. Extreme irritability of the nasal passages, as evinced by paroxysms of sneezing, frequent spasmodic closure of one or both nostrils, abundant transudation of watery fluids, etc., can often be relieved by rubbing the septum and anterior turbinated in the manner described.

CLINICAL MEMORANDA.

NERVE-GRAFTING OR TRANSPLANTATION FOR PARALYSIS RESULTING FROM INJURY TO THE MUSCULO-SPIRAL.[1]

BY CAPTAIN A. E. BRADLEY, M.D.,
ASSISTANT SURGEON U. S. ARMY; FORT YELLOWSTONE, WYOMING.

I. W., private, Troop "B," Tenth Cavalry, stationed at Fort Custer, Montana, by a fall from his horse on April 11, 1895, fractured his right humerus at about the junction of the upper and middle thirds.

The case was seen by the writer a few days after the injury was sustained, through the courtesy of Captain Egan, at that time post surgeon at the post. The fracture was oblique, involving probably about two and one-half inches of the shaft, extending from without, downward, inward, and forward. It was complicated from the first by paralysis of the extensors of the forearm, the characteristic "wrist-drop" of musculo-spiral paralysis. Loss of function of the group of muscles supplied by this nerve seemed complete. The fracture healed promptly under appropriate dressings, with good union, no deformity, and little or no shortening.

The paralysis persisted, and up to the time the case came under my care, about May 20th, had not improved with massage and battery treatment.

At this time the muscles of the whole arm were atrophied from disuse; muscular excitability of the forearm-extensor group could be elicited by percussion and a slowly interrupted galvanic current. Until operation these muscles were given electrical stimulation three or four times weekly, with no perceptible improvement.

After much difficulty in gaining the consent of the patient, operation was performed June 22, 1895, with the assistance of Assistant Surgeon Kennedy, U. S. Army.

A medium-sized dog was secured, and under anæsthesia his sciatic nerve was antiseptically isolated and left in situ surrounded by warm sterilized gauze; the operation was then begun by a three-inch incision over the depression between the biceps and triceps muscles, and the nerve found with no difficulty in the musculo-spiral groove. It had been thought that rupture had been complete; but the nerve was continuous, having at the seat of injury a hard nodular enlargement apparently involving the whole trunk, about one centimetre in diameter and two centimetres in length. This, and the nerve itself on either side for some distance, were intimately adherent to the callus, and dissected loose only with much difficulty; the line of fracture corresponded to the nodule.

After mature deliberation it seemed advisable to remove the tumor, which was done, provisional sutures being first introduced, so as easily to control the two ends for further manipulation. Efforts were then made to bring the ends into approximation by stretching, but the space was too great; about three centimetres had been removed, and the retraction of the two ends about doubled this distance.

A section of the previously prepared nerve of the dog, five centimetres in length, was carefully sutured in place with fine catgut, there being no traction on the sutures when the approximation was completed. The wound was then closed and dressed. Modern surgical methods were strictly observed throughout.

The recovery from operation was perfect; union took place by first intention; there was no pain, no fever, nothing abnormal.

During the next four weeks he received faradic treatment to the muscles involved three or four times a week. Because of changes of station he passed from observation late in July. Recent information from Major Shannon, Surgeon U. S. Army, who relieved the writer at Fort Custer, states that there being no improvement observed, he was finally discharged from the service for disability.

The time between operation and discharge was too short to decide fairly as to whether or not function would have been ultimately restored, and the operation physiologically successful. The writer thought that sensation was returning before four weeks had elapsed, and believed that the prognosis was favorable.

It is to be regretted that the case could not have been kept under observation for five or six months at least.

The section removed was examined by Major Reed, Surgeon U. S. Army, Curator of the Army Medical Museum, and he has kindly made the following report:

"Referring to my letter of July 15th, concerning the tumor of musculo-spiral nerve removed from a soldier, I beg to submit a further report of the microscopical examination.

"Its general structure is that of a soft fibroma, moderately rich in cells. In the middle part of the section there are seen cross-sections of four nerve-bundles. Within the bundles no nerve-fibrils are to be made out, their place being taken by a connective tissue fairly rich in cells.

"At one margin of the section there are seen cross-sections of five other small nerve-bundles. While in two of these bundles no cross-sections of nerve-fibrils are to be made out, in the other three one can still see, here and there, fibrils with normal-staining axis-cylinders; in other words, the section shows a marked hypertrophy of both the perineum and endoneurium of the nerve-bundles, and hence the tumor might properly be designated as a traumatic fibro-neuroma."

Efforts to find the patient so as to procure a later report have been unavailing.

The subject of nerve-suturing, etc., has been carefully gone over by Dr. Willard, of Philadelphia, in an excellent paper appearing in THE MEDICAL NEWS, October 6, 1894.

He mentions several cases of nerve-grafting with varying results; his conclusions, however, are that when the loss of nerve-substance is large nerve-grafting will usually give better results than the splice-operation of splitting and turning the nerve-flaps into the gap.

REPORT OF A CASE OF ŒDEMA OF THE GLOTTIS, FOLLOWING SCARLET FEVER.

BY JOHN GRAHAM, M.D.,
OF PHILADELPHIA.

CASES of œdema of the glottis, especially in children, are sufficiently rare to justify me in reporting the following case:

On November 4th I was called to see Annie H., and found her suffering from an attack of scarlet fever of moderate severity. She was put to bed, her diet regulated, and bowels kept open daily. Her throat, which was red and swollen, but free from false membrane, was sprayed with an atomizer containing Dobell's solution.

On November 10th she was convalescent, and I ceased my visits, giving the usual directions in regard to diet, avoidance of exposure, and pointing out the chief symptoms that indicate the coming on of albuminuria.

On the night of December 1st, three weeks after my last visit, I was called in haste, and found the child suffering from marked dyspnœa. She was sitting up in bed, making long, but not loud, sounding inspirations. There was marked supra- and infra-clavicular retractions with each inspiration. There was no cyanosis, but the child looked pale and anxious.

The lungs gave forth a clear sound on percussion, and there was an almost total loss of vesicular murmur, but no râles. There was not, and had not been, any croupy or loud cough.

The mother informed me that our patient had been taken suddenly ill, with difficult breathing, a few hours before my arrival; that up to that time she had continued to improve since my last visit, excepting that for one week past she had lost her voice, and could speak only in a whisper; and that for the past twenty-four hours the child had passed only a few drops of urine. The mother had fortunately saved the small amount voided, and on testing it with heat and nitric acid it showed a large amount of albumin present. The patient's temperature was 99°. There was no dropsy of the face, feet, or legs.

By a poor light, and using a spoon for a tongue-depressor, I examined the throat, with negative results. There was no false membrane in sight. I could see the tip of the epiglottis, but could not see the glottis. I saw no swelling or redness. I did not attempt to examine the glottis with my finger to find if it were swollen, because such an examination would have increased the dyspnœa. I had no mouth-gag to protect me from the child's teeth, and only an expert can derive positive information from such touch; but lastly, and for the most important reason, the absence of such swelling would be only negative evidence, for so-called œdema of the glottis in most cases is really œdema of the larynx, and there may be but little swelling of the glottis.

My diagnosis at the time was probable œdema of the glottis, and the subsequent history of the case, I think, clearly proved it correct.

I explained to the mother that her child was suffering from a disease similar to membranous croup, and that, to give time for our medicines to act, it might be necessary to perform tracheotomy to save the child from smothering.

I ordered pulv. jalapæ com. ʒj to be given to the child in divided doses, the entire amount to be taken inside of one hour; tincture of digitalis, 5 drops every three hours; and a mixture containing 2 grains of carbonate of ammonium and 10 m. of syr. senegæ every two hours. The diet to consist of milk, in as large quantities as the child could take without producing vomiting, and to use whiskey in the milk should symptoms of exhaustion come on.

This treatment was followed in six or eight hours by copious watery evacuations from the bowels and a free action of the kidneys, and coincident with these discharges the dyspnœa began to abate, and our patient steadily improved until December 7th, when the albumin had entirely disappeared from the urine.

With the disappearance of the albuminuria the child's voice returned clear and strong, showing that this symptom, which had existed for one week before my first visit, had been probably caused by œdema.

No false membrane was ever seen in the throat or expectorated.

From the time dyspnœa abated, and for one week after, the child expectorated, with slight cough, a quantity of thin, watery mucus, streaked with blood, averaging a teaspoonful at each expectoration. She complained of no pain in the throat, and there were no mucous râles in the lungs at any time during the illness.

To recapitulate the symptoms on which I based my diagnosis—

1. A cause for the œdema—albuminuria.
2. The absence of false membrane at the beginning and throughout the attack.
3. No croupy or metallic cough, and almost normal temperature—never above 99°.
4. Dyspnœa on inspiration, and not noticeable on expiration. True croup shows dyspnœa on inspiration and expiration.
5. The result of treatment.
6. The characteristic expectoration following the abatement of the dyspnœa.

MEDICAL PROGRESS.

Hysterical Hemianopsia in a Case of Epilepsy after Trephining.— At the recent Congress of French Alienists and Neurologists, LANNOIS (*Mercredi Médical*, 1895, No. 52, p. 615) reported the case of a man who developed attacks of focal epilepsy after trephining for the removal of fragments of bone broken by a blow upon the right side of the head by a leaden cane. After a series of convulsive attacks the man presented hemianopsia, with profound anæsthesia and loss of the muscular sense upon the left side. After a time the anæsthesia became segmental and disappeared suddenly in the course of an electrical séance, the hemianopsia being at the same time replaced by a narrowing of the visual fields.

Syphilitic Pneumonia.—At a meeting of the Moscow Dermatological Society, POSPELOW and KONTRIM (*Monatsh. für prakt. Dermatologie*, 1895, No. 12, p. 644) each reported two cases of syphilitic pneumonia that yielded to treatment with mercurials. Hæmoptysis occurred in three of the cases, and fever with sweating was present in two. The lesion was localized to the apices. In one of the cases tubercle-bacilli were found in the sputum, and the process was believed to be tuberculous. Treat-

ment with mercurial inunctions and sulphur-baths, with a residence in Egypt, was followed by general improvement and disappearance of fever, cough, and expectoration. The patient had been well for three years at the time of the report. In this case it is believed that the tuberculous affection was implanted upon the syphilitic pneumonia, disappearing with the latter.

Two Primary Carcinomata in the Same Individual.—At a recent meeting of the Berlin Medical Society Israel (*Berliner klinische Wochenschrift*, 1896, No. 2, p. 45) reported the case of a woman, fifty years old, who came under observation on account of gall-stones, for the relief of which the gall-bladder was incised and its walls attached to the abdominal wall and fifteen concretions evacuated. Death took place suddenly several days after the operation as a result of heart-failure, which upon post-mortem examination was found to be due to mitral stenosis. In the wall of the gall-bladder was found a large area of ulceration surrounded by thickening of the adjacent tissue. Microscopic examination disclosed the histologic structure of a cylinder-cell carcinoma in places scirrhous. The cystic duct contained a polyhedric stone of cholesterin. The head of the pancreas was further found to contain a cancroid tumor as large as a hen's egg. The retroperitoneal glands presented secondary involvement of cylinder-cell character.

The Correction of Wandering Spleen by Splenopexy.—As the result of a study of the physiologic functions of the spleen in conjunction with an experimental investigation, Sykoff (*Archiv für klinische Chirurgie*, Band li. Heft 3, p. 637) concludes that extirpation of the spleen under otherwise favorable conditions is only successfully possible when the remaining blood-forming organs are in a normal state. When local affections of the spleen exist resection is to be undertaken in preference to splenectomy. Splenectomy is indicated when the pathological alteration of the spleen is not secondary but primary, and capable of further extension throughout the organism; and when it cannot be hoped that the pathologically affected spleen (however slight the involvement may be) will perform its physiologic function. A wandering spleen should be fixed in position. For this purpose catgut-sutures will answer admirably. The organ thus attached diminishes in volume—an advantage if it be hypertrophied. In case of anterior displacement of the spleen an attempt should be made to return the organ to its proper place and fix it there.

Successful Cœliotomy in a Case of Obstinate Dysentery.—At a recent meeting of the Medical Society of Amsterdam Stephan (*Berliner klinische Wochenschrift*, 1896, No. 1, p. 21) presented a man, twenty-six years old, who, eight weeks before coming under observation, was seized with fever and looseness of the bowels, the intestinal evacuations containing blood and pus. The condition thus continued, the patient losing flesh and growing anæmic. There was some tenesmus, but the abdomen was only slightly distended. Upon palpation a painful band was appreciated in the left side of the lower portion of the abdomen. There was irregular slight elevation of temperature. In the diagnosis tuberculosis, syphilis, and carcinoma were excluded and dysentery decided upon. The use of many different drugs directed to the treatment of the condition named last was unattended with successful results. It was therefore finally determined to perform cœliotomy and establish an artificial anus. Through this opening local treatment by means of an emulsion of bismuth, with later tannic acid, and ultimately silver nitrate was instituted. Improvement soon set in, and in the course of a few months it became possible to close the artificial anus.

THERAPEUTIC NOTES.

In the Treatment of Frostbite, Montmollin (*Rev. Méd. de la Suisse Rom.*, 1895, No. 12) has employed successfully baths of the affected parts of from fifteen to thirty minutes' duration, four times daily, in a centesimal solution of tannic acid, together with baths twice daily for fifteen minutes in soap-water.

For Bronchitis in the Aged.—Take of

Benzoic acid	5 grains.
Tannic acid	2½ " —M.

Make into a cachet. Dose: Take four or five in the day.—Maragliano, *Gaz. Hebd. de Méd., etc.*, 1896, No. 1.

To Prevent Iodism from the use of potassium iodide, Spencer (*Jahrb. f. prakt. Méd.*, 1895) employs the following formula:

Take of

Potassium iodide	℥j.
Iron and ammonium citrate	℥j.
Tincture of nux vomica	f℥ij.
Distilled water	f℥j.

Compound tincture of cinchona to make f℥iv.—M.

Dose: A teaspoonful three times a day in water after meals.—*Monatsh. f. Derm.*, 1896, No. 1.

For Dry Pharyngitis.—

℞.—Acid. carbolic.	gr. iv.
Tinct. iodi	♏v.
Tinct. aloes	♏viij.
Tinct. opii	gtt. x.
Glycerini	f℥j.—M.

S.—Use as a spray several times daily.—Danet, *Progrès Médical*, No. 51.

The Treatment of Epilepsy with a Combination of Potassium Bromide, Adonis Vernalis, and Codein.—As the result of a rather extended clinical study of the utility of a combination of potassium bromide, adonis vernalis, and codein in the treatment of epilepsy, Taty (*Lyons Médical*, 1895, No. 12; 1896, Nos. 1, 2) arrived at the conclusion that the addition of codein is not an advantage, as to this must be attributed the resulting constipation and somnolence, while bromism is thus not avoided. The adonis acts as a stimulant to the heart and increases the flow of urine, although it does not prevent the hebetude or the attacks.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

No. 111 FIFTH AVENUE (corner of 18th St.), NEW YORK.

Subscription Price, including postage in U. S. and Canada.

PER ANNUM, IN ADVANCE	$4.00
SINGLE COPIES	.10
WITH THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, PER ANNUM . . .	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, FEBRUARY 8, 1896.

THE TRANSFER OF THE MEDICAL NEWS.

THE management of THE MEDICAL NEWS has reason to be flattered with the discussion which has arisen over its transfer from Philadelphia to New York, and with the degree to which gentlemen, apparently not concerned in the subject, have taxed their ingenuity in inventing causes to account for it. The matter would seem to be so simple as to be self-evident. THE NEWS has never been a mere local journal. Large outlays and unremitting labor have been lavished on it to obtain and maintain for it a national and even cosmopolitan position. These efforts have been crowned with success. Wherever the English language is read THE NEWS is recognized as an organ of the profession at large and not of that of a single city or State. It has welcomed and has been favored with contributions from every part of the country and of the civilized world. Its subscription list is equally extensive, and of recent years it probably has had as many readers in New York as in Philadelphia. If Philadelphia has supported it generously with contributions and subscriptions, so have New York and Boston and Cincinnati and Chicago and all other centres of professional activity, and it has sought to recognize this favor by payment to contributors, the only medical periodical, we believe, in the English language that makes it a rule to do so, with the exception of the *American Journal of the Medical Sciences*.

When, therefore, the increasing business of the publishers rendered it expedient for them to open a branch of their establishment in New York, in order that the authors, whose works they have the honor to publish, should have the benefit of the business facilities of both cities, it was natural that they should transfer one of their periodicals. The selection fell on THE NEWS, because, as partaking of the character of a medical newspaper, the concentration of activity in New York seemed to offer greater opportunities to it than to the *American Journal of the Medical Sciences*. Whether its office be in one city or the other, it will expect to receive, as heretofore, the support of the profession at large, and if, as its managers anticipate, the business advantages of New York shall enable it to acquire a wider sphere of influence, it will be able to offer to its readers an increased store of information, and to its contributors a larger opportunity of disseminating their views throughout the world.

THE DANGER OF SEPSIS IN ENDERMATIC INJECTION (INFILTRATION-ANÆSTHESIA).

THE growing popularity of infiltration-anæsthesia since its discovery in 1891 by Schleich, of Berlin, and subsequent introduction into Germany and America one and a half years ago, makes it necessary to sound a note of warning regarding its indiscriminate use without proper care as to the technique. The only substantial objection to this form of local anæsthesia that has been raised is that of the possibility of infection from septic fluids, unclean hands or instruments.

There are certainly many physicians who either do not clean their hypodermatic syringes, or simply wipe them off and then go to the next patient. It is not customary to make special preparation of the skin or of the hypodermatic needle for ordinary hypodermatic injection. Even the fluid in which to dissolve the morphine, the cocaine, or other tablet, is not always drawn from an aseptic source. Moreover, the small amount of serum which clings to the needle on withdrawal is certainly a culture-medium for the streptococcus, and becomes a fruitful source of inoculation for the succeeding patient.

It is remarkable that we see or hear but little of hypodermatic abscess, which, despite septic injection, must be an uncommon occurrence. We can only ascribe this to the fact that in hypodermatic injection the fluid is deposited in a comparatively compact depot under the skin. It therefore does not readily diffuse itself into the tissue, and thus permits of rapid phagocytosis.

Quite different is endermatic injection; for when fluid is slowly infiltrated into the tissues it distends the meshes, replacing the fluids and the blood entirely for a length of time (ten to twenty minutes). The infiltrating fluid is brought intimately into relation with the cellular elements, and phagocytosis does not obtain in time to counteract the effect of implantation of septic germs which can thus gain a foothold, and more certainly cause suppuration than in ordinary hypodermatic injection.

A case of sloughing has been brought to the writer's notice in which the Schleich method was used for anæsthesia in operation for mammary abscess. The infiltration-fluid was prepared by a local druggist; the infiltration was made by the physician with a hypodermatic syringe and needle used for ordinary medicinal injection. "Anæsthesia was complete, but operation was followed by sloughing of the whole surface of the skin injected."

Schleich does not report any such accident at his hands. Nor has Würdemann met with a single case of the kind in his practice, although he reports several hundred injections. Reports coming from other surgeons do not chronicle such immunity, which can only be the fault of the operator. Schleich has pointed out in his brochure and in his other writings that absolute sterilization of everything in connection with the procedure should obtain. Würdemann insists that to insure uniform success it is important to apply scrupulously the following rules: I. The ingredients of the solution should be made absolutely sterile. This may only be obtained by *boiling all the solutions for five minutes before each operation* (afterward cooling same). This factor is especially pertinent, as several leading American and European manufacturing chemists have infiltration-tablets on the market for extemporaneous preparation of the several fluids. The tablets themselves are presumably aseptic, but if fingered ever so slightly cannot remain pure. *Boiling the solutions after mixing does not interfere with their anæsthetic qualities.* II. The bottles containing the solutions and all receptacles for the fluid should be previously boiled (or sterilized by heat), and not suffered to remain exposed to contaminating influences, not even the air, but should be covered after cooling.

It is even more necessary for instruments to be aseptic than for ordinary operations. Any good hypodermatic syringe and needle may be used, but should be previously prepared by immersion for at least one-half hour in a 5 per cent. carbolic solution, which may be removed before operation by washing in sterilized water. The finest and sharpest of needles are advisable. These may be sterilized by boiling in soda solution or by carbolic immersion.

The person preparing the solution as well as the surgeon should prepare his hands as carefully as if for an abdominal operation. The part to be operated upon should be made aseptic in the usual manner. Attention to detail is absolutely necessary for the success of healing as well as for anæsthesia.

This is such a valuable method of anæsthesia and is receiving such wide application in the hands of our best operators that for the benefit of those not familiar with the procedure we append the following bibliography:

Schleich, A.: 1. Verhandlungen der Berliner Medicinischen Gesellschaft, 1891. 2. Verhandlungen der Deutschen Gesellschaft für Chirurgie, 1892. 3. Berliner klinische Wochenschrift, 1892. 4. Schmerlose Operationen Monograph, Berlin, 1894.

Van Hook W.: 5. The Value of Infiltration-anæsthesia. THE MEDICAL NEWS, November 16, 1895.

Würdemann, H. V.: 6. "Explanation and Demonstration of the Infiltration (Schleich) Method of Anæsthesia. Journ. Amer. Med. Assoc., December 29, 1894. 7. "The Infiltration Method of Anæsthesia in Ophthalmic Practice." Journ. Amer. Med Assoc., November 16, 1895.

THE STATE CARE ACT.

By the approval of the Mayor and the signature of the Governor the Act of the Legislature transferring the insane of the county of New York to the State, the "State Care Act," goes into full effect. All the dependent insane of all the counties will henceforth be supported by the State in the State Hospitals. This Act adds 7329 to the number of the insane in State care, making a grand total of upward of 20,000. The transferrence of the insane of this county to the care and support of the State will prove a great benefit to the taxpayers of this city. It will lighten the burdens of taxation to the extent of more than $1,500,000 annually, but it remains to be seen how the people of the State will regard the heavy burden which

is imposed upon them by the Legislature. The State Comptroller estimates that the pauper insane will be a tax upon the State beginning with $1,000,000 annually, and the cost will steadily increase as the number of these dependents increases. Of this fact, however, we are well assured, viz., the insane in the institutions of this city are to be greatly benefited by the change. The wretched and incompetent management of the asylums of New York had rendered them little else than institutions for the conversion of the acute into the chronic insane.

THE LIBRARY OF THE NEW YORK ACADEMY.

THE library of the Academy of Medicine of this city has become a permanent institution of which the citizens may well be proud. It has passed the period of random growth and is now enlarging on a well-constructed plan, which is destined to make it one of the most complete medical libraries of the world. As a working library for medical and surgical writers it is now scarcely inferior to the Surgeon-General's Library at Washington. The Council of the Academy has always shown a most commendable liberality in sustaining the library. But, like all libraries, its future growth and usefulness depend upon a permanent endowment fund, which shall enable its managers to meet every prospective emergency. An effort to meet this want is about to be made, largely through the influence of the President, Dr. Bryant, which we trust will be eminently successful. The committee of twenty-five, whose appointment was noticed in our previous issue, have already begun work.

ECHOES AND NEWS.

DR. JOHN H. HUBER, Coroner's physician, has sent in his resignation. There are already fifteen applications for the place with Coroner Hoeber.

THE will of the late Dr. Robert G. Remsen, as filed in the Surrogate's office, shows that Dr. Remsen left personal property valued at $1,000,000 and real estate of the value of $150,000.

THE mortality of the State of New York is a trifle higher for 1895 than in 1894. The rate is stated as 19 per 1000 of population. Typhoid fever and diphtheria claimed 1270 and 5000 victims, respectively.

THE Board of Managers of the new Manhattan State Hospital—the new name of the New York City Asylum—are soon to be appointed by Governor Morton. The new Board is to consist of seven members, two of whom shall be women.

TWO butter-makers and the son of Allen Devereaux, whose tuberculous herd of dairy cows was recently destroyed, have contracted the disease. As all were large partakers of the diseased milk, there can be little doubt as to the source as well as the method of their infection.

ALTHOUGH there are several factories in the vicinity of New York devoted to the preparation of horse-meat for food, it is comfortable to be reassured by the chemist of the Board of Health that not an ounce of it is sold in this city unless it be in the shape of imported sausage. It is also stated by these authorities that the flesh of the horse is easily detected by the usual iodine-test for starch, which it contains in contradistinction from all other butchers' meat.

REPORT comes from the University of Michigan of the adoption of a rather novel procedure in the surgical clinic of Dr. Carrow. The case was that of a young man afflicted with a disease which caused the complete loss of sight in one eye. In order to prevent the contagion spreading to the well eye, a watch-crystal was inserted under the lid of the unaffected eye. No impurities can now enter from the outside, and the patient is able to see very well through his novel monocular.

THE tracheotomy-tube has found a new use in overcoming the insufficient breathing-capacity of race-horses. Since the great horse Ormond was condemned as a roarer, attention has been called to the prevalence of this malady among thoroughbreds, and resort has been had to tracheotomy with admirable results. The statement is made that at the recent Manchester races in England three of the four best steeplechasers carried silver tubes in their windpipes.

A CHICAGO ham containing a large consignment of trichina has escaped the vigilance of the export officers and found its way to Antwerp, Belgium, where it is doing much in a small way to disturb our peaceful international relations. At all events, this missive from our pork-proud city of the West will not serve to increase the mutual esteem of the two municipalities, and therefore even the most innocent-looking ham should not receive a passport without the microscopic inspection required by law.

THE success of Roentgen's method of photographing the deeper structures of opaque objects continues to excite the deepest interest. Like so many great discoveries, it needs only to be mentioned to be understood. Bullets and other foreign substances in the flesh and bones of patients have already been located successfully in innumerable instances. Perhaps the most interesting success thus far is that recorded in the news from Vienna, where Dr. Neusser showed the position of calcareous deposits in the bladder, liver, and kidneys of patients. Professor Trowbridge, of Harvard University, is also experimenting successfully with the method.

TESLA, the distinguished electrician, has directed his inventive genius into the medical field. He has produced a machine which he calls an oscillator, and its effect, briefly stated, is to produce a shaking up of the human system (thus following the idea of Charcot), thereby causing certain physical conditions and alterations of forces, which will give energy and force to parts

but partly used. He has also produced an artificial light which under certain conditions is powerful enough to penetrate the human body. Metzuer, of Vienna, claims to have discovered that by its use the bacilli of tuberculosis may be destroyed.

The New York State Medical Society held a meeting of unusual interest last week. The following officers and committees for the ensuing year were elected: President, Dr. J. D. Spencer, Jefferson County; Vice-President, Dr. L. Duncan Bulkley, New York City; Secretary, Dr. F. C. Curtis, Albany; Treasurer, Dr. Charles E. Horton, Albany. Committee on Legislation, Drs. Walter Suitor, Herkimer; M. J. Levi, New York City. Committee on Prize Essays, Drs. A. Jacobi, New York City; Henry Hunt, Albany. Delegates to the British Medical Association, Drs. Charles L. Dana, New York City; James P. Boyd, Albany; John P. Bigelow, Albany; M. Allen Starr, New York City.

The resolutions adopted at the above-mentioned meeting, recommending that a bill be prepared and presented to the Legislature to secure the placing of all private medical institutions for the treatment of cancer and other diseases under the care of the State Board of Health, is a long step toward the proper legal oversight and control of many retreats, concerning which the public at present know nothing, except what their proprietors voluminously set forth in almanacs and kindred literature. New York is afflicted with more than her share of these institutions, and they richly deserve State attention.

Impure Ice and the Health Commissioner.—Health Commissioner Munn, of Denver, is having trouble with the courts of his county. It seems that the bacteriologist of the city found a great number of bacteria in ice sold by a particular company, and accordingly the company was requested to stop the sale of such ice, and on their refusal to do so the persons composing the company were brought before the magistrate and fined. The company, however, still continued to carry on their business, and the commissioner ordered the business stopped.

The county court was appealed to by the company, and they succeeded in obtaining an order from the judge restraining the commissioner from interfering with its business, and also a judgment against him for the costs of the suit. They claimed that no complaint had been entered against them; that there was lack of evidence; that the measure was unjust, oppressive, illegal, and tyrannical; that the pretended ordinance under which the commissioner acted was unreasonable, unconstitutional, and in restraint of trade; that he exceeded his jurisdiction and abused the discretion lodged in him.

On the other hand, the commissioner claims that the ice was obtained from a filthy pond near the city, and was sold as pure lake ice; that the bacteriologist pronounced it unsafe for human consumption; that, according to an ordinance of the city, "The health commissioner may condemn, or cause to be destroyed, any fluid or substance intended for food or drink, whenever he is satisfied that its consumption might be dangerous to health." This, of course, gives the commissioner exceptional and absolute powers—the Board of Health of Philadelphia and other cities have similar authority—and yet it is essential to the health of a community that some such constituted body should have the power to decide summarily in such questions. As the commissioner well states, this cannot be left to a court or jury, "they could not determine whether the ice was impure better than the experts selected by the city." And if the health boards cannot restrict an unsanitarily conducted business because it would be an interference with commerce, they might as well give up their office, since to prevent a milkman from selling impure milk or a manufacturer from allowing goods to be made in unclean sweat-shops is a restriction of trade. One might as well ask the chief of the fire department to obtain an order from the court before he be allowed to cut down trolley wires or break windows when a fire occurs.

It is necessary, of course, that the men who are given such absolute powers be chosen for their fitness and not because of political sympathy. Commissioner Munn, of Denver, Colorado, is in every way capable, and his appeal to the courts of the State will, no doubt, be successful, and they will sustain him in his efforts. The decision of this court will be awaited with much interest by the various municipal health boards and health commissioners, as it will more clearly define the power they are entitled to use.

Digestion in Plants.—It is natural to have a pretty high opinion of anything that belongs to ourselves. While we have admitted for some time past that some very wonderful processes and things were to be found in the organization of the lower animals and plants, yet we have always had a feeling of conscious pride that the term "fearfully and wonderfully made" applied with special and unique appropriateness to the mechanism of our own bodies. Our complex and elaborate digestive system, for instance, is a case in point. It was a great blow to our *amour propre* to find that it was duplicated in every detail in the stomachs of our animal cousins, but we still clung to the facts that we had more kinds of digestive ferments than any other species, and that while we might deign to admit kinship with animals in this respect, we were still immeasurably superior to plants of any sort. We are just beginning to submit to the epithet "animal" as applied to ourselves without worse protest than a half-suppressed growl, but the mere suggestion of any vegetable affinity —"cabbage-head" or "pumpkin," for instance—will cause an instantaneous contraction of the *arrectores pilorum* over the whole length of our dorsal aspect.

But even this barrier behind which our pride has entrenched itself, must also go down. No less distinguished authorities than Prof. Marshall Ward and Pentland Smith have discovered a vigorous starch-digesting or diastatic process in the grains of the familiar maize and the tubers of the lowly potato. In both cases so soon as the bud or shoot begins to develop it secretes a ferment that attacks the starch of the mass and changes it into sugar for absorption by its growing cells. It is this conversion and rapid absorption of the starch that cause the familiar shrinking and shrivelling of potatoes that have sprouted in the cellar. Thus it seems clear that we shall have to "acknowledge the corn"—as one of our relatives.

But worse is to follow. Not only can this wretched cereal do with ease what our salivary glands and pancreas strain themselves red in the face over, but it also

performs another feat that our elaborate human digestive apparatus is utterly incapable of, and that is, dissolve or "peptonize" cellulose or woody fiber. The starch needed by the shoot for conversion is enclosed in cells with firm walls of cellulose, and these must be eaten through before it can be acted upon by the diastatic ferment. Accordingly another ferment is secreted that dissolves cellulose as our pepsin does proteids.

Of the helplessness of our own ferment in the presence of cellulose we have all had personal and painful demonstration in the extraordinary vagaries indulged in by the festive cucumber and the frugal raw turnip when introduced into our unsuspecting and defenceless interior.

In fact, the peptonizing power of the vegetable ferment is so much greater than that of the animal that, as we see daily, the papayotin of the pineapple, the pawpaw, and other fruits are rapidly becoming commercial rivals of the porcine product.

Certain other plants display even more strikingly human characteristics in that they have actually become meat-eaters and meat-digesters. It has long been known that a large family of flowering plants of which the "Sundew" and "Venus' Fly-trap" are familiar examples, secrete upon the surfaces of their leaves a thick, sticky juice, which in the former simply entangles insects, and the latter attracts and holds them till they can be actually seized by the halves of the leaf closing upon them trap-fashion. Whether these were utilized in the nutrition of the plant was, however, an open question until quite recently, when a series of analyses of this viscid secretion was made, and it was found to contain both a peptic ferment and an acid, which together rapidly dissolved all the soft tissues of the insects, leaving only the wings and hard cuticular casing of the body and limbs. And what makes the resemblance to our own gastric processes most striking is that neither the acid nor the ferment is present in any quantity in the resting condition of the leaf, but both are poured out as soon as nitrogenous matter is placed upon the surface.

Truly our pedigree is of wonderful length, and we must regard ourselves not only as "magnificent animals," but as superb vegetables. If our physiologic processes are so strikingly similar, what a flood of light may vegetable pathology be expected to throw upon our disease-processes!

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninetieth Annual Meeting, Held in Albany, January 28, 29, and 30, 1896.

(Concluded from page 139).

ROSWELL PARK, M.D., of Buffalo, President, in the chair.

FIRST DAY—JANUARY 28TH (EVENING SESSION).

DR. GRACE PECKAM-MURRAY, of New York, in a paper on

TETANOID HYSTERIA,

said that by tetany she understood a disorder characterized by spasms of an intermittent character, which during the intermissions could be produced by pressure over a principal nerve-trunk or bloodvessel of a part. She then reported three cases typical of the three varieties given by Trousseau—the benign, the medium, and the severe. In those rare cases in which there was a fatal termination this was due to spasm of the diaphragm and other respiratory muscles.

DR. NATHAN JACOBSON, of Syracuse, read a most interesting and timely paper, which will appear in our next issue, on the

TREATMENT OF MALIGNANT DISEASE IN SO-CALLED CANCER-INSTITUTIONS,

and called forth the resolution of the Society asking for State inspection and supervision.

DRS. L. D. BULKLEY, F. W. SHAFFER, and others said that from what they had learned from experience they could heartily indorse the statements contained in this paper.

DR. H. R. HOPKINS, of Buffalo, made some remarks on

ALCOHOLISM AND PUBLIC HEALTH,

in which he scored the recent bill providing for the compulsory teaching of the children in the public schools regarding the effects of alcoholics and narcotics, and dwelt particularly on the fact that the same body of persons that had secured the passage of this pernicious bill had also succeeded in securing similar legislation in forty States.

DR. A. W. SUITER, of Herkimer, introduced a resolution, which was adopted, to the effect that the Committee on Legislation be instructed to use all honorable effort to bring about a repeal of or an essential modification of this law.

DR. J. H. HUNT, of Brooklyn, with the aid of lantern-slides, delivered an address on

THE EVOLUTION OF PATHOLOGY,

and showed portraits of many of the great men of past ages who had contributed to this branch of medical science.

SECOND DAY—JANUARY 29TH.

In executive session, among other resolutions approving of certain recommendations in the President's inaugural address, was one regarding the relation of the Society to the American Medical Association. In adopting this resolution it was stated that the Society was ready to co-operate in any plan compatible with the dignity of both organizations, whereby the interests of professional harmony and the liberal spirit of the age would be advanced.

The following resolution was also adopted: That the Committee on Legislation be directed to secure the passage of a bill by the Legislature whereby "cancer-institutions" should be placed under the care of the State Board of Health in the same manner as private institutions for the care of the insane are under the care of the State Commission in Lunacy.

DR. W. E. FORD, of Utica, read a paper on

VAGINAL HYSTERECTOMY BY CLAMPS.

He said that hysterectomy was certainly not an elective operation for suppurative disease of the tubes and ovaries in most instances. Vaginal hysterectomy had

been done with clamps years ago and abandoned for ligatures, but Jacobson, of Brussels, had claimed, and substantiated this claim with statistics, that with properly constructed instruments the vaginal operation with clamps was the safer one. The disadvantages were that the presence of clamps in the vagina was a source of discomfort to the patient, and there was danger of too free oozing of blood. This second objection might be partially, at least, overcome by using instead of gauze-packing the cylindrical pledgets used abroad. The chief feature of Jacobson's operation appeared to the author to be the skilful use of the peculiar forceps and scissors. Recovery was much more rapid after the vaginal operation.

Dr. A. Vander Veer, of Albany, read a paper, entitled

COMPLICATIONS IN ABDOMINAL SURGERY REQUIRING INTESTINAL ANASTOMOSIS, AND THE BEST METHOD OF DOING THE OPERATION.

He reported three cases as illustrative of the type of emergency-cases often met with, and of the need in such of rapid surgical as well as efficient surgical methods. It was in just this class of cases that the Murphy button was especially useful, notwithstanding that there were certain real dangers associated with the use of this method, such as the retention of the button. For incised wounds of the intestine, and for gunshot-wounds of the bowel, if of small calibre, the Lembert suture or some other method of intestinal suture without mechanical device was appropriate. Of all the methods of intestinal suture that had been proposed, he thought Maunsell's method was the one most likely to be generally adopted.

Dr. D. Mann, of Buffalo, read a paper on

SLOUGHING OF UTERINE FIBROIDS AFTER ABORTION AND LABOR.

He said that under the stimulus of pregnancy fibroids previously of slow growth often became formidable complications. In a series of 597 cases, in which no treatment had been adopted for this complication, death had occurred in 220 cases. Owing to the distortion of the uterine canal, there is always great danger of sepsis.

Dr. H. J. Garrigues, of New York, read a paper on

THE TECHNIQUE OF THE IMPROVED CÆSAREAN SECTION,

he recommending doing the operation, if possible, just before the expected time of labor, and having present four assistants. After attending to the usual precautions regarding the cleansing of the patient, the instruments, and the hands of those engaged in the operation, an incision was to be made in the median line half above and half below the umbilicus. After turning out the uterus and closing the upper part of the incision, a rubber constrictor is to be loosely applied around the cervix and broad ligaments and crossed. After properly guarding the abdominal cavity from contamination, the constrictor is tightened, the uterus incised in the upper part for four or five inches, and an effort made to deliver the head of the child before the uterus has contracted in front of it. The cord is tied and cut, and if the placenta remains adherent after the uterine sutures have been inserted, it is to be peeled off with the membranes. In suturing, it is better to keep the peritoneum outside of the muscular layer. The interior of the uterus is cleansed by wiping, and the elastic ligature very gradually loosened. All oozing having ceased, the uterus is returned to the abdomen and an antiseptic dressing and bandage applied. The bowels are moved on the third day.

Dr. W. Gill Wylie, in opening the general discussion on the foregoing papers, spoke of the abdominal *versus* the vaginal operation. He said he would rather have 10 per cent. of ventral herniæ and have 25 per cent. remain in bed for many weeks than have an increase of even 1 per cent. in the death-rate, and for that reason he had preferred the abdominal operation. He had, it was true, employed the vaginal route in 105 cases, but the good results he was inclined to attribute to these cases having been selected. He did not favor morcellation in the removal by the vagina of uterine fibromata.

Dr. Herman J. Boldt, of New York, said that where the uterus was situated high and was quite firmly fixed ligatures could not be used, but where the uterus was movable and there was but little inflammation in the adnexa the ligature-operation was suitable. It was not at all necessary to leave the clamps on longer than twenty-four hours. Total extirpation of the pelvic organs should be resorted to only where there were recurrent pelvic inflammations or suppurative processes.

Dr. M. D. Mann, in referring to intestinal operations, said that as the element of time had not seemed to him to be so important as Dr. Vander Veer would have us believe, he had preferred the intestinal suture to the use of the Murphy button. In suturing he had found that time could be saved by taking four stitches of continuous suture, then interrupting it, and tying. He had become deeply impressed with the great value and importance of the vaginal operation, but the danger of intestinal fistulæ with this operation fully offsets the liability of ventral hernia following abdominal section.

Dr. W. G. MacDonald, of Albany, said that he preferred to pass a hook around the broad ligament and pull it down. This gave the forceps good control of the ligament. He objected to a multiplicity of clamps in the field of operation, nor was it necessary by this method of operating.

Dr. A. H. Goelet thought the popularity of vaginal hysterectomy depended chiefly on its novelty, and in support of this assertion enumerated a number of the disadvantages of the vaginal method. He admitted, however, that it had a limited field of usefulness.

Dr. J. Riddle Goffe, of New York, in discussing Dr. Ford's paper, said that he had been greatly interested in the vaginal method of operating. He believed that in cases of bilateral disease in the pelvis, if the ovaries and tubes were hopelessly diseased, the uterus was no longer of use, and would be better out of the way. This additional procedure, he found, did not increase the mortality, and the operation was made much easier. He had met with two cases recently in which the appendages had been removed through Douglas's pouch, and the uterus left behind. They had come to him shortly after operation with symptoms of infection, and examination had shown the uterus to be full of pus. The original focus of disease had evidently been in the uterus

in these cases. The matter of using clamps or ligatures seemed to him largely a matter of individual preference.

DR. A. T. BRISTOW said that in many cases, as in the one of strangulated hernia described in Dr. Vander Veer's paper, the element of time was extremely important; hence the use of some mechanical device appeared to him essential. All the methods of intestinal suture were slow, and required much expertness.

DR. B. FARQUHAR CURTIS, of New York, favored suture where the case was not extremely urgent, but where rapidity of operating was an essential, the Murphy button was better. It was objectionable in cases of gastro-enterostomy on account of the liability of the button falling into the viscus.

DR. WILLY MYER, of New York, read a paper on

EARLY DIAGNOSIS OF TUBERCULAR KIDNEY.

This will appear in a subsequent issue of THE MEDICAL NEWS.

DR. REYNOLD W. WILCOX, of New York, read a paper entitled

THE SYMPTOMS AND DIAGNOSIS OF THE INDIGESTION OF STARCHY FOODS,

which will also appear in a subsequent issue.

DR. BULKLEY, in discussing this paper, emphasized the importance of proper mastication, and of the avoidance of imbibing fluids along with the food.

DR. T. HALSTED MYERS, of New York, read a paper on

CONGENITAL DISLOCATION OF THE HIP,

and exhibited a patient upon whom he had successfully operated. He said that the Lorenz operation was safe if the operator was sufficiently skilful and employed thorough asepsis, and that even when it failed to cure it left the bone in a position of greater stability, and hence the usefulness of the limb would be improved. The little girl upon whom he had successfully operated was four and a half years of age, and had been delivered after a difficult labor. Nothing abnormal had been noticed until she began to walk. Last February the shortening was found to be one and a half inches, and she presented all the symptoms of congenital dislocation of the hip. Under ether, the dislocation was forcibly reduced and the limb put up in plaster-of-Paris spica, with the limb abducted about thirty degrees. Last July the present splint had been applied. It exerted pressure against the trochanter and held the limb abducted. Motion at the hip, knee, and ankle was allowed. The shortening was now about one-fourth of an inch; there was no telescoping and no pain. This apparatus would be worn by the child for another year.

DR. EDWARD D. FISHER, of New York, read the opening paper on a

DISCUSSION OF THE PRESENT STATUS OF THE SURGERY OF THE BRAIN.

He said that the indications for operation were: (1) traumatism; (2) localized epilepsy; (3) athetosis; (4) tumors; (5) abscess; (6) cerebral hemorrhage; and (7) microcephalus. In cases of epilepsy he favored the bone-flap operation; in tumor, he preferred the removal of the bone with trephine and rongeur. He had been unable, even after careful observation, to detect any shock due to the concussion produced by operating with mallet and chisel. Many of these cases were so miserable, and without hope, that even though such operations were only occasionally successful, they would be justifiable.

DR. M. ALLEN STARR, of New York, followed with a paper on

BRAIN-TUMORS.

He said that the two great obstacles to operating on brain-tumors were the difficulty of accurately locating them and the difficulty of reaching them. It is only when the tumor is small and lies upon, but does not involve, the cortex, that the prognosis can be said to be absolutely good. Out of 162 operations, 48 were cases in which no tumor was found; 7 in which the tumor was found but not removed; 35 in which the tumor was removed and the patients succumbed; and 72 in which the tumor was removed and the patients recovered. He also preferred the flap-operation.

DR. CHARLES L. DANA, of New York, read a paper on

THE VALUE OF CRANIOTOMY FOR IMBECILITY AND EPILEPSY.

He had found after excluding the older operation, which did not fairly represent the surgery of the present time, 22, of which 6 had been improved, 10 unimproved, and 6 died. Congenital idiots and imbeciles were the two classes most likely to be benefited by operation of this kind, and the most that could be expected was a mental and physical improvement. He felt convinced that the operation produced its effect by its profound impression and consequent disciplinary influence.

DR. B. SACHS, of New York, read a paper on the

SURGICAL TREATMENT OF EPILEPSY.

He said that in New York City, at least, operations for the relief of this condition were much less frequent than formerly. Such surgical interference was particularly indicated before degeneration had taken place. Young children do not bear such operations at all well.

DR. JAMES W. PUTNAM, of Buffalo, read a paper on

CRANIOTOMY,

in which he referred to the more encouraging experience of Buffalo surgeons in this class of operations. It could not be denied that but few were benefited, but even this small hope was worth an effort when one considered the pitiable condition of the individuals for whom relief was asked.

DR. GEORGE WOOLSEY, of New York, continued the discussion. He said that in only one of his eight operative cases could it be strictly said that a cure had been effected. He favored operating with carvers' chisels, ground upon their outer surface.

DR. WILLY MEYER, of New York, read a paper on

HETEROPLASTY, WITH CELLULOID TO COVER DEFECTS IN THE SKULL,

in which he described his experience with this particular material. He had had difficulty in obtaining the celluloid in sufficiently thick plates, but now that obstacle had been surmounted.

DR. JOSEPH COLLINS, of New York, thought that the preceding speakers had presented too gloomy a view of the present status of cerebral surgery. It should be

borne in mind that operation was the only hope of relief in purulent infiltration of the brain, which in 35 per cent. of all cases was the result of chronic purulent otitis.

Dr. Floyd S. Crego, of Buffalo, spoke in much the same strain. He believed that a very common error was made by surgeons in failing to continue medical treatment after the operation. In his opinion it should be persisted in for two years.

Dr. E. B. Angel said that there was no necessity for performing heteroplasty, as the deficiency was filled in with very dense fibrous tissue.

Dr. W. C. Krauss, of Buffalo, read a paper on the

TREATMENT OF SCIATICA WITH NITROGLYCERIN,

in which he said that this line of therapeutics had yielded him so much better results than other methods of treatment that he felt impelled to advocate its trial in all cases of sciatica before resorting to other medication. He reported seven cases which had been markedly benefited by the administration of nitroglycerin in doses of 1 minim of a 1 per cent. solution three times daily. He did not claim that it cured *every* case, but only a fair percentage.

Prof. James H. Etheridge, of Chicago, delivered an address on

DEFICIENT EXCRETION FROM KIDNEYS NOT ORGANICALLY DISEASED IN SOME OF THE DISORDERS PECULIAR TO WOMEN,

which will appear in a subsequent issue of The Medical News.

Dr. Bulkley said that fifteen years or more ago he had incidentally discovered that the course of eliminative treatment employed by him in most cases of skin-disease not infrequently exerted a marked influence on menstrual irregularities and difficulties. This had happened so frequently that some of his patients had brought to him other members of the family simply to have them treated for menstrual disorders. That his treatment was essentially that laid down in the paper was shown by the fact that it was his habit to prescribe fifteen grains of acetate of potassium, with a little cascara and nux vomica, before each meal, using as a vehicle the extract of rumex.

At the evening session Dr. Roswell Park, the President, delivered his anniversary address, taking for his theme

THE VALUE OF THE COMPARATIVE METHOD IN THE STUDY OF PATHOLOGY.

(See The Medical News, February 1st, page 113.)

THIRD DAY—JANUARY 30TH.

Dr. W. G. MacDonald, of Albany, read a paper on

THE REORGANIZATION OF THE CORONER'S SYSTEM.

He recommended the appointment of a medico-legal officer by the Appellate Division of the Supreme Court, for a term of five to seven years. This officer would thus be removed as far as possible from politics, and his duties would be entirely medical, the legal portion being attended to by the usual court machinery.

Dr. Rudolph Witthaus, of New York, said that it was hoped that with the co-operation of the State Bar Association this Society would be able to have passed through the present Legislature a bill having provisions similar to those recommended in Dr. MacDonald's paper.

Hon. Tracy C. Becker, Drs. Balch and H. Bender all spoke in much the same strain, and, on motion, the President was requested to appoint an auxiliary committee of twenty-five or more.

Dr. W. Browning, of Brooklyn, read a paper on

DEVELOPMENT OF MUSCULAR ATROPHY ON A BASIS OF OLD INFANTILE SPINAL PARALYSIS, A FAVORITE TYPE.

He said that his experience in this class of cases had warranted him in drawing the following conclusions: (1) that infantile spinal paralysis is sometimes followed by further atrophy at a subsequent period; (2) that the assumption that it is due to extension of the cord-affection could not be accepted in most instances; (3) in the young some other peripheral affection is present; and (4) disuse, poor nutrition, and exposure are powerful etiological factors.

Dr. M. A. Veeder, of Lyons, read a paper on

NEURITIS COMPLICATING DISLOCATIONS OF THE SHOULDERS AND ELBOWS.

He said that the ulnar and median nerves were liable to become involved in dislocations at the elbow, and the symptoms varied according as the trophic, motor, or sensory filaments of the ulnar nerve were involved. At the shoulder the impairment of the muscles might lead to a recurrence of the dislocation almost spontaneously when the arm was placed in certain positions. Sometimes the full effect of the damage done to the nerve might not appear for several months. In dislocation of the humerus, the axillary structures were apt to be put on the stretch, and if the elbow were pulled out from the body, a powerful leverage would be exerted in such a way as to increase this traction on the axillary nerves. Massage and electrical treatment were of service.

Dr. W. Hailes, of Albany, read the histories of two cases of

DIFFICULT PERINEAL AND SUPRAPUBIC LITHOTOMY.

Dr. M. L. Foster, of New York, read

SOME NOTES ON TRACHOMA.

He objected very strongly to the use of the term "granular lids," which not only had no very definite meaning at the present time, but served to give the impression that the case was incurable, when, in fact, it might be perfectly amenable to treatment. He preferred the term "follicular conjunctivitis." Regarding the disputed germ-origin of this condition, he said that at present there was no positive evidence that it was due to micro-organisms.

A number of other papers were read by title.

President Wilson, of the Board of Health of New York City, strongly recommends that all rear tenements be abolished as a constant and uncontrollable source of disease. There are more than 2500 of these damp, filthy, and ill-ventilated buildings which house a population of nearly 60,000 people.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, January 16, 1896.

Joseph D. Bryant, M.D., President, in the Chair.

THE BACTERIOLOGY OF EMPYEMA IN CHILDREN.

Dr. Henry Koplik said that the bacteriology of pleuritic exudates had been materially advanced in recent years. There were several varieties of empyemas in children, *e.g.*, (1) meta-pneumonic; (2) streptococcus empyemas; (3) tubercular empyemas; and (4) fetid empyemas. In meta-pneumonic pleurisies the pneumococcus might from the outset attack the pleura with great severity, while the resulting pneumonia might be so slight as not to give rise to noticeable symptoms. In a series of fifteen cases of empyema in children he had found that in nine, or 6 per cent., the diplococcus of pneumonia was present in pure culture. In a little over 3 per cent. of the meta-pneumonic pleurisies the streptococcus was also present, but did not appear to affect the prognosis. Empyema in children may arise from a slight streptococcus-infection of the throat, or a slight wound-infection, but in those empyem as which are associated with severe sepsis, as in scarlet fever, the streptococcus is very virulent and the prognosis is accordingly more grave. The tubercular empyemas are not so frequent as the meta-pneumonic and streptococcus varieties, but as a rule the prognosis is bad. They are accompanied by great thickening of the pleura. The fetid empyemas might be conveniently divided into (1) those due to a streptococcus- or pneumococcus-infection, and (2) those due to mixed infection. The speaker said that in his experience those empyemas in children in which there had been an attempt at spontaneous cure by perforation through a bronchus were very prone to be fetid. In children fully two-thirds of the empyemas are meta-pneumonic.

THE DIAGNOSIS AND PECULIARITIES IN CHILDREN.

Dr. August Caillé said that in children the infection of the pleura was very frequently secondary, and that exposure to cold could only be considered a predisposing cause of empyema. Of eighty cases coming under his notice, sixty-seven had been in children under five years of age. Probably one-third of all the pleurisies occurring in early life are purulent or sero-purulent, and in gangrene of the lungs or in pyothorax due to traumatism the empyema is apt to be of the fetid variety. The change of a simple pneumonia into a pleuro-pneumonia should not be difficult to recognize. In the former the child cried freely without exhibiting any sign of pain; in the latter it was quite apparent that crying and coughing, and even the act of respiration, were painful. Inspection would show lateral curvature of the spine, bulging or retraction of the intercostal spaces on inspiration, displacement of the heart; but all these signs would not be present in every case. Moderate dyspnœa and bulging of the affected side were, however, usually present in cases of pleuritic effusion. The fever was apt to be irregular, but might be altogether absent, as in cold abscesses elsewhere. In cases of pleuritic effusion palpation would show bulging of the intercostal spaces on inspiration, and an absence or diminution of vocal fremitus. In some instances there would only be a diminution of the fremitus as compared with another part of the thorax, and in any case to detect the change in the fremitus it was necessary to make the child cry. On auscultation, if there were a sufficiently thick layer of fluid between the lung and the ear, the respiratory sounds would be diminished, but tubular breathing might be heard over the fluid, being transmitted from the compressed or inflamed lung-tissue. Diminished vesicular breathing and fremitus with dulness would point to thickening of the pleura. Where the effusion was considerable, egophony might be audible in the axillary line. Bronchophony would be heard over the consolidated lung, but not over the fluid. Percussion would reveal flatness over the area of fluid effusion, and would also impart to the finger used as a pleximeter a distinct feeling of unusual resistance. It should be remembered that in children an apparent dulness on the right side posteriorly is not necessarily pathological. If the percussion were made quite forcibly, the resonance of the underlying lung might be brought out. When there is sufficient fluid to compress the lung the lower portion of the chest will be flat on percussion, and there will be an absence of breath-sounds; while over the upper portion there will be an increase in the respiratory sounds. The change in the level of the fluid resulting from causing the patient to change his position is not easily detected in young children. The only way to make a positive diagnosis of fluid pleuritic effusion in a little child and of determining the nature of this fluid is by puncture with an aspirating-needle. Before doing this the site of the proposed puncture should be made surgically clean, and then, with the child's arm held upward, a clean needle is plunged into an intercostal space to the depth of one or two inches. Unless the character of the fluid is perfectly apparent, it should be subjected to microscopical examination. On the withdrawal of the syringe the puncture should be dressed with adhesive plaster or gutta-percha tissue. There is no danger of injuring the liver if the puncture on the right side is not made below the eighth intercostal space. Even in desperate cases an incision should be promptly made after establishing the diagnosis of empyema, and it should be borne in mind that even in those cases in which a perforation into a bronchus has already occurred the pus will frequently not escape until the intrathoracic pressure has been relieved by an incision into the chest. The only satisfactory explanation of the manner in which the lung is reinflated after such an opening has been made into the chest is, that it is due to the mechanical effect of coughing, the air being driven in the direction of the least resistance, which in this case is from the sound to the crippled lung.

THE TREATMENT OF EMPYEMA IN CHILDREN.

Dr. Joseph E. Winters said that the natural history of empyema furnished the indications for treatment, and these were to remove the pus, prevent reaccumulation, procure complete expansion of the lung, and prevent deformity of the chest. An empyema got well, not by healing from the bottom, but by the expansion of the lung and the ascent of the diaphragm, and consequently the removal of a portion of the pus by aspiration prior to incision was harmful, as the diminished

pressure so produced made the expansion of the lung more feeble. It was by this expansion of the lung that the fluid was expelled from the thorax. As soon as the inflammatory process had subsided an incision should be made into the chest. In his opinion, it was because of the earlier diagnosis and treatment of this condition at the present time, rather than because of improved methods of treatment, that the mortality from empyema had been so reduced. He felt that at present there was too great a tendency to resort to resection of one or more ribs in recent cases of empyema. This operation was not indicated in such cases, because we did not desire a falling in of the chest until after the lung had fully expanded, and, moreover, resection of the rib was followed by a much higher mortality than was simple incision.

Where there was no cyanosis present, the incision into the chest might be done under an anæsthetic, and for this purpose chloroform was preferable, but the anæsthesia should be only partial in order that the patient might cough and aid in the expulsion of the pus. Before making the incision an aspirating-needle should be inserted, and if this detected fluid the needle should be left in place and used as a guide to the knife in making the incision. This incision should be at least two inches long, and should be made two to three inches above the base of the normal thoracic cavity. During the operation the patient should be placed on the affected side and close to the edge of the table. In this position it was possible to irrigate the pleural cavity carefully and safely and so remove coagula. Hot water should be used for this purpose. The speaker favored giving the child immediately after the incision had been made a teaspoonful of whiskey, undiluted, as when thus given it acted as a stimulant and also excited cough and crying. During convalescence massage and systematic chest-exercises were useful, and experience had shown that forced expiratory effort, such as occurs in blowing wind-instruments, was an efficient aid in securing complete expansion of the lung.

Dr. A. Jacobi said that while he concurred in the statement that as the diagnosis of empyema had been more promptly made, the term "chronic pneumonia" had been less frequently heard, he wished to call attention to the fact that an interstitial pneumonia was of common occurrence in children, and was responsible for a persistence of the symptoms and physical signs long after the usual time. Persistent fever and dulness after an ordinary pneumonia might not, therefore, mean a secondary empyema, but the occurrence of an inflammatory peribronchial infiltration, which might very properly be termed a chronic pneumonia. These symptoms, under such circumstances, might last for six or eight weeks.

Dr. B. Scharlau said that on looking over his hospital-records for the past five years he found that he had performed resection of the ribs for empyema between one and two hundred times—in fact, after a fair trial of other methods of treatment, he now did this operation to the exclusion of all others. He did this because such a line of treatment seemed to him more in accordance with the principles guiding us in the treatment of other abscesses and because complete recovery was more rapid after rib-resection than after other treatment. He had found that in about 50 per cent. of the cases of empyema there were present coagula which were too large to escape through the small incision ordinarily made. Some of his patients had recovered in ten days after resection of a rib, and it was not at all uncommon for recovery to be complete in three weeks, whereas after simple incision convalescence usually occupied six or eight weeks. He had never found that the resection of a portion of the rib led to malformation of the chest. Most of those who advocated simple incision had never given rib-resection a trial.

Dr. W. P. Northrup said that his observations on empyema had been for the most part on children under three years of age, and next to tubercular meningitis he considered the diagnosis between fluid effusion and pneumonia in an infant of eighteen months the most difficult. The most important physical signs were one-sided dulness and the absence of vesicular breathing. He frequently found it impossible for him to distinguish the bronchial breathing occurring in connection with a moderate effusion from that associated with pneumonia. From these considerations, it followed that one must early resort to the use of the aspirating-needle in many cases, and in doing this it was most important that the result of this procedure could be relied upon, which was not true, unless a needle of very large calibre was employed, and inserted in two or three places, if the first puncture proved to be negative. The site of puncture and the needle should, of course, be carefully sterilized. After careful observation on many cases he felt warranted in saying that the drainage of the cavity would be perfect, no matter how the incision into the chest was made. It was ordinarily well to select the sixth intercostal space, and in children under two years of age the incision should be made nearly two inches in length, and two drainage-tubes should be inserted side by side. The practice at the present time did not seem to be in favor of resecting a rib in these young children.

Dr. Henry D. Chapin said that he did not know of any other common disease of childhood in which so many little ones lost their lives as a result of a tardy diagnosis as in empyema. The younger the subject the more difficult was it to understand the physical signs. In his experience there was no bulging of the chest with a moderate fluid effusion, and this was probably due to the fact that the lung, and not the chest-wall, furnished the least resistance. Bronchial respiration was commonly heard all over the fluid. As the majority of cases of empyema in children seem to follow pneumonia, the physician should be ready to make exploratory puncture as soon as it is evident that the symptoms and signs of pneumonia are persisting for an unusual time. A large needle should be employed. If in the course of such a pneumonia we found beginning dulness at the apex, there was good reason for believing that an effusion into the pleural cavity had occurred, and had pushed up and compressed the lung. He had tried rib-resection in a few cases, but in some of these, as in the hands of surgeons of known experience, sinuses had persisted; and, as his results from simple incision had been satisfactory, he could see no good reason for resecting a rib in infants.

The President being called upon for an expression of opinion on this point, stated that his experience had convinced him that recovery was more rapid after rib-resection.

Dr. Floyd M. Crandall said that two important facts had been elicited by this discussion, viz.: (1) That empyema in young children was almost always secondary, frequently to pneumonia; and (2) that the diagnosis of this condition in such young patients was very difficult. These facts should teach us to be charitable to brother-practitioners who happen to make mistakes in the diagnosis of these cases.

Dr. Caillé said that irrigation of the pleural cavity had been almost abandoned, because it broke up the adhesions between the lung and thoracic wall.

Dr. Winters said that he was very much opposed to resection of a rib in these cases as a primary procedure, because in children under two years of age the death-rate from this operation was 80 per cent., whereas after simple incision it was only about 25 per cent. Recent personal inquiry had elicited the fact that in most of the hospitals of Europe this practice of resecting a rib in cases of empyema had been abandoned. He was also of the opinion that the difficulty of making the diagnosis of empyema in young children had been exaggerated, for if the examiner was careful to make the patient inspire deeply, the sound was totally different from that produced by consolidated lung.

REVIEWS.

Cutaneous Medicine, a Systematic Treatise on the Diseases of the Skin. By Louis A. Duhring, M.D. Part I. Philadelphia: J. B. Lippincott & Co., 1895.

The appearance of a new systematic treatise on diseases of the skin by Dr. Duhring is an event of much importance in the history of American medicine. In the year 1876 this distinguished clinician and author gave the world what was then the most condensed practical and trustworthy text-book on dermatology extant, and its signal merits were so much appreciated abroad that it was translated into the French, Italian, and Russian languages, and was very widely read. In America three large editions were published, the last of which appeared in 1882. It thus happens that this book was the chief source from which most American students derived their knowledge of skin-diseases. Now, after a period of twenty years, during which Dr. Duhring has zealously devoted himself to his chosen line of study, he lays before us this mature work, which promises to be one of the most important additions to American medical literature ever published, and which will readily take an assured position beside similar works of foreign authors. The scope of this work, of which we have now the first part, containing 220 pages, is laid on broad, practical, and conservative lines. In his preface Dr. Duhring says:

> The author is convinced that the skin occupies a more conspicuous place in medicine than has heretofore been accorded to it. It is a large, complex, important organ of the body, and is by no means a mere protective covering. It is not only subject to many diseases which are wholly confined to the skin, but it is also intimately connected with numerous general morbid processes, to describe and to point out the significance of which is within the province of cutaneous medicine.

In the part now published the groundwork of dermatology is considered, and in each section we find the subjects treated in a careful, clear, and ample manner. The author, while he gives his own views in detail, is exhaustive in his presentation of the facts and opinions held by all accredited authors. There is evidence on every page of deep and broad research and mature thought. We do not find a mere categorical statement of facts and opinions, but, what is necessary in works of this class, a thorough and judicial study and sifting of all statements, followed by a lucid and homogeneous presentation. The chapter on the "Anatomy of the Skin" is exhaustive, occupying fifty-two pages. It is very clearly and simply written, and the text is illustrated by a very large number of figures drawn by the most experienced authors in histologic and pathologic anatomy. The physiology of the skin is likewise treated in a thorough manner.

The section on "General Symptomatology" is so full, comprehensive, and clear that it will be a great aid alike to the student and general physician. The same remarks apply to the sections on etiology, pathology, treatment, and prognosis.

While the work is almost exhaustive, it is written in such simple and clear language that its perusal is a pleasure rather than an effort.

The Art of Compounding. A Text-book for Students and a Reference-book for Pharmacists at the Prescription-Counter. By Wilbur L. Scoville, Ph.G., Professor of Applied Pharmacy and Director of the Pharmaceutical Laboratory in the Massachusetts College of Pharmacy. 8vo. pp. 255. Philadelphia: P. Blakiston, Son & Co., 1895. Price, $2.50.

This is a book for the pharmaceutist rather than for the physician, although it deals with a number of matters with which medical men could with advantage be familiar. It were really a desideratum that the practising physician should know, both theoretically and practically, more than he does concerning the physical properties of the drugs that he uses, and that he should have a working familiarity with the methods employed in their compounding, together with the results of this process. That physician is a better prescriber, not to say therapeutist, who has an understanding of the science and art of pharmacy. To these ends the book in hand will aid. It will, however, find its greatest field of usefulness among pharmacists and students of pharmacy, and to these it is to be warmly commended. As is well pointed out in the introductory remarks, "Skill involves . . . first, mental knowledge and the power to rightly apply it, and, second, manual dexterity." These objects will be furthered by a judicious use of this book.

An Atlas of Ophthalmoscopy, Etc. By Dr. O. Haab. Translated and edited by Ernest Clarke, M.D., B.S., London. New York: William Wood & Co., 1895.

We are glad to have in English and in so handy a form Haab's pictures of the eye-ground. With a few exceptions they are excellent, and give most faithfully the appearances seen with the aid of the ophthalmoscope. We cannot help wishing that there had not been attempted the so-called shot-silk retina. It is impossible to repro-

duce in the first place, and this special attempt should warn all others hereafter against such an undertaking. If the bull may be pardoned, we have never seen the papilla so utterly invisible, as here represented, in the early stages of optic neuritis. The text accompanying the illustrations is printed in three different positions upon the pages, so that one is provoked to be compelled to reverse the holding of the book with every alternate turning of the leaves. There is an introduction of about fifty pages concerning the ophthalmoscope, methods of examining the eye, etc., which will be found of use by students.

A Text-book of Chemistry, intended for the use of Pharmaceutical and Medical Students. By Samuel P. Sadtler, Ph.D., and Henry Trimble, Ph.M. 8vo. 922 pages and index. Philadelphia: J. B. Lippincott Co.

It must be regretted that the authors of this book decided to attach the word "medical" to its title. Such a term can have only a commercial significance, for the book is not written from the standpoint of the medical chemist. Of its excellence as a manual of general chemistry and of its value to students of pharmacy and industrial chemistry it is needless to speak. Its authors are too well known as successful teachers and investigators in these departments to leave any doubt as to the character of their present work. It is true, also, that such a term as "medical chemistry" is rather arbitrary, since the facts and theories of the science have universal application, but it is also true that in the exigencies of modern medical teaching it is necessary to develop in considerable detail some phases of chemistry, while others are not to be so extensively discussed. All sciences may be viewed from the point of their practical use, and there will be different perspectives for different points. In the present work the perspective is not that of either the medical teacher or student. There are two pages devoted to the manufacture of alizarin and a page and a half devoted to a description of the ptomaïns. The chapter on qualitative analysis is devoted wholly to the usual system of detecting acids and bases by routine tests. No description is given of the tests used in clinical work, nor does toxicology receive any more than passing notice.

We have noted above that as a manual of general chemistry it is highly commendable. We think it a little bulky. Students are able to use books printed with smaller type than this, and it is an advantage to have a handy volume for college-uses. Since the authors are both actively connected with pharmaceutic work, it is to be expected that they should follow the *Pharmacopœia* closely. The work is well printed and contains a large amount of information.

The Evolution of the Diseases of Women. By W. Balls-Headley, M.A., M.D. (Cantab.), F.R.C.P. (London), Lecturer on Midwifery and the Diseases of Women in the University of Melbourne, etc. Pp. 375. London: Smith, Elder & Co., 1894.

The scope of this book is unique, in that it is concerned with the evolution and natural history of various pathologic processes in women. In the words of the author, the plan "is to show the states of the sexual relations as they have evolved in the human race, and the position at which they have now arrived, with their causations and influences on woman; and to trace their influence through their progressive stages, so far as they have tended in the direction of disease. Also to indicate the mode of prevention of such causes of disease, and of such disease not only in the social but also in the medical aspect." Much of unwritten medicine, it will be seen from the foregoing quotation, must be touched upon in the volume, and this has been accomplished in a modest and acceptable manner. It is presented in the first portion of the book, while the etiology, symptomatology, prognosis, and prophylaxis of the commoner gynecologic conditions comprise the bulk of the remainder of the work. In describing these various pathologic conditions the author endeavors to elucidate the course or evolution of the morbid processes, but naturally in many instances does not succeed in doing so, owing largely to the paucity of our knowledge of these diseases. Aside from the laws of sexual hygiene, which are rather fully entered into, and which in most books on gynecology are largely ignored, there is but little new in the book. The style is fair and the reading interesting, but as far as practical usefulness is concerned but little can be said. There is absolutely nothing in the line of therapeutics except a few general directions at the close of the volume. The author has evidently had in mind a theory which he has not been able to present in a satisfactory manner, and some of the views advanced as to the evolutionary nature of the various processes considered are not altogether acceptable, at least in this country.

Physical, Intellectual, and Moral Advantages of Chastity. By Dr. M. L. Holbrook, Editor of the *Journal of Hygiene and Herald of Health*. New York: M. L. Holbrook & Co.

This is a well-written little book of 120 pages, in which the author aims to set forth a high ideal of life, and instead of dilating on the evils of unchastity to point out the advantages of chastity. It is a book that can be placed in the hands of the young of both sexes with profit to them, and physicians by recommending it will show that they do not encourage the commonly held opinion that for young men at least abstinence from sexual intercourse is prejudicial to health.

Indurative Mediastino-pericarditis. By Thomas Harris, M.D., F.R.C.P. London: Smith, Elder & Co., 1895.

Dr. Harris has written a most interesting monograph upon the subject indicated by the title, reporting a number of cases and analyzing the literature. Pathologically he recognizes three classes of cases of chronic inflammatory conditions involving the pericardium and mediastinum. Class I. comprises the cases properly termed indurative mediastinal pericarditis, in which there are adhesions to the surrounding parts, and not unfrequently caseous affection of the lymphatic glands of the mediastinum. Class II. is more frequent, and includes those cases, sometimes termed pericarditis externa and interna, in which the sac is thickened and adhesions have formed to surrounding parts, but with very

little general mediastinitis. Class III. comprises instances of fibrous mediastinitis without any internal pericardial adhesions.

He recognizes the inability in many cases to distinguish clinically one of these pathologic forms from another, though the third class may be distinguished from the other two during life, at least in some instances.

The author then proceeds to report three cases (one of each class), which were followed systematically from an early stage to the termination and post-mortem examination. He tabulates twenty-two additional cases collected from the literature, including only such as contained both the clinical and pathological examinations. It is impossible to detail as fully as we could wish the facts established by this most interesting little work, but we commend it warmly as a careful study in clinical pathology.

An Elementary Course in Experimental and Analytical Chemistry. By John H. Long, M.S., Sc.D., Professor of Chemistry and Director of the Chemical Laboratories in the Schools of Medicine and Pharmacy in the Northwestern University. Small 8vo. 497 pages and index. Chicago: E. H. Colegrove & Co.

We are pleased to recognize in this manual another evidence of the tendency to abandon the use of a course in qualitative analysis for practical instruction for beginners in chemistry. Dr. Long rightly observes that the system gives a distorted view of the relative importance of that department of chemistry. The complex problems set for the student in the usual qualitative course are not representative of the actual work either of research or commercial analysis. The classification by means of the so-called "group-reagents" is not a scientific one, but a purely arbitrary arrangement for a narrow practical purpose.

In the present work Dr. Long devotes over two hundred and fifty pages to the experimental part; that is, detailed directions for performing two hundred and twenty-six experiments, exhibiting the properties of elements and important compounds, and the general principles of chemistry. There are but twenty-two illustrations in this part, and most of these are not particularly commendable. We think it would be wise to illustrate such works quite freely, selecting the simplest apparatus, and to give a preliminary chapter of some length on the forms and uses of the standard articles, test-tubes, dishes, etc.

In the section on qualitative analysis the usual group-reagents are used. There are also chapters on spectroscopy, toxicology, and volumetric analysis. The decimal system of weights and measures is employed. The work is well printed.

Medical and Surgical Report of the Children's Hospital, 1869–1894. Edited by T. M. Rotch, M.D., and Hubert L. Burrell, M.D. Boston: Published by the Board of Managers, 1895.

This handsome volume of 367 pages is published with the view of presenting to the community, first, the history of an institution organized and maintained for the care of sick and disabled children; secondly, in order to show, by the contributions of the members of its medical staff, how much good work has been done, and the most efficient methods known to medical science of accomplishing its object; and, thirdly, of offering carefully prepared articles, based largely on the practice of the hospital, on various topics of importance in the science of medicine. For this purpose the matter is divided into three parts, under the headings "Administrative," Medical," and "Surgical." Of these the last takes up fully two-thirds of the volume, and presents quite a comprehensive view of this branch of the hospital's work and of its method of treatment. Orthopedics naturally holds a prominent place, and is quite fully illustrated. The medical division embraces only seven short papers, which, however, are of unusual interest. It is to be regretted that greater space was not devoted to this portion of the hospital's service.

The volume is a handsome specimen of book-making, and is creditable alike to the institution whose work it thus brings to public notice, and to the various members of the staff whose unselfish labors have made the hospital what it is to-day.

A Manual of the Practice of Medicine. By George Roe Lockwood, M.D., Professor of Practice in the Woman's Medical College of the New York Infirmary, etc. 8vo. pp. 935. Philadelphia: W. B. Saunders, 1896.

We think that the author of this *Manual* has succeeded in his aim to present "the essential facts and principles of the practice of medicine in a concise and available form," although we cannot encourage his hope that it "will meet the requirements of those who heretofore have been obliged to resort to the larger works of reference, with which medical literature is so well supplied." We believe that there is greater need for the "larger works" in the higher medical education of the day, and that the supply is none too large, although the lesser can be made to serve a useful purpose as adjuvants to this end. For the manner in which the author has performed his task we have only words of commendation. Within a comparatively limited space he has succeeded in reciting clearly and tersely the essentials relating to the practice of medicine, and on the whole he has displayed good judgment in his attitude toward debatable questions. By the use of thin paper of good quality, the volume has been kept within reasonable proportions, and the clearness and size of the type, as well as the typographic arrangement and the press-work, make the reading easy. Of the illustrations, many are well executed, but most are not new.

We rather doubt the accuracy of the statement that "a few cases of typhus fever occur every year in New York and Philadelphia." No reference is made to the efficacy of pilocarpine in the treatment of erysipelas. In the treatment of appendicitis small doses of opium are recommended, while cathartics are interdicted. The designation "hysterical peritonitis" seems not a very happy one, for an inflammation of the peritoneum could not well be hysterical. A better term would perhaps be "pseudo-peritonitis," with or without qualification.

FIG. 6.—Ankylosis of terminal phalanges. Enlargement of second phalanx. (Arthritis in living subject.)

FIG. 5.—Polydactylism with webbed fingers. Osseous union at tops of three phalanges. Extra phalanx at side. Outer and inner carpal bones double, the separation between left bones and the adjacent phalanges being discovered by this process. (Living subject, left hand.)

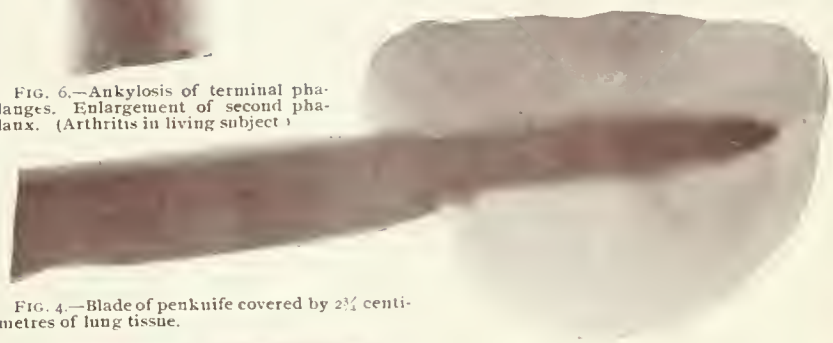

FIG. 4.—Blade of penknife covered by 2¾ centimetres of lung tissue.

FIG. 1.—Small intestine containing cent, lead-pencil and gall-stone. The latter being organic matter is very indistinct.

FIG. 3.—Piece of rib covered with cirrhotic liver one centimetre thick.

FIG. 7.—Hand of cadaver. Two bullets inserted from palmar surface; piece of glass beneath round bullet. Lateral luxation of terminal phalanges of ring finger. Amputation of middle finger. Crush of central portion of index finger.

RÖNTGEN-PICTURES OF MEDICAL SUBJECTS,

Taken by HENRY W. CATTELL, M.D., in the Physical Laboratory of the University of Pennsylvania, with the kind permission of PROF. ARTHUR W. GOODSPEED.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, FEBRUARY 15, 1896. No. 7.

ORIGINAL ARTICLES.

ROENTGEN'S DISCOVERY.

BY ARTHUR W. GOODSPEED, PH. D.,
OF PHILADELPHIA;
PROFESSOR OF PHYSICS IN THE UNIVERSITY OF PENNA

PROBABLY never before has the entire scientific world been simultaneously aroused to such a pitch of excitement as that caused by the recent remarkable discovery of Professor Röntgen, of Würzburg, that it is possible to produce photographic effects through opaque substances such as wood, ebonite, flesh, and similar dense materials, while glass, which we customarily regard as the most transparent of media, obstructs the passage of the cathodal ray.

If we speak of light as that portion of radiation which is capable of affecting the eye, the new agent, or the X-ray, as the discoverer calls them, is certainly not light, and "photographic" is evidently not the word to apply to the effects produced.

As it seems probable that this exhibition of energy is either a form of radiation or is intimately related to it, the term *radiography* might with propriety be applied to the process of producing the impressions.

The earlier reports from abroad indicated that the use of two induction coils were necessary, the secondary of one be connected with the primary of the other, and that a Crookes' "radiant matter" tube be connected with the secondary of the latter. As glass proved comparatively opaque it was deemed advisable to have a small aluminum window in the tube through which the rays could more easily pass. Later experiments, however, prove conclusively that these refinements are not needed, though without them a much longer exposure—perhaps an hour or more—is required. A single induction coil run by a few storage cells will excite an ordinary Crookes' tube quite enough to produce most of the results yet published. The induction coil in its ordinary form is familiar to every practitioner. A much larger coil is needed than is used for physiological stimulation, that which is being used in the experiments at the physical laboratory of the University of Pennsylvania being about 12 inches long and $4\frac{1}{2}$ inches in diameter. It was constructed by Apps, of London, and possesses a primary resistance of about 0.3 ohm and a secondary resistance of about 3,200 ohms. The Crookes' tube represents as complete a vacuum as it is possible to obtain, and is supposed to have an interior pressure of about one-millionth of an atmosphere. The negative electrode from which the X-rays start is an aluminum disc about a half-inch in diameter. With the apparatus at present used by the writer an exposure of an hour or more was allowed. An ordinary photographic camera is used, having an aluminum shutter, which remains closed. The sensitive plates are entirely enclosed in the photo-holder, which is placed about five inches from the end of the Crookes' tube, in a horizontal position on the table. The subject to be *radiographed* is placed on the cover of the plate holder. The plates are developed and fixed in the usual manner. Radiograms to any extent may be printed upon any sensitized paper.

ROENTGEN'S DISCOVERY ITS APPLICATION IN MEDICINE.

BY HENRY W. CATTELL, A.M., M.D.,
OF PHILADELPHIA;
DEMONSTRATOR OF MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA.

RÖNTGEN'S weird and wonderful discovery is destined to enrich medicine with possibly the most valuable diagnostic process which recent years have witnessed. Within a month from Röntgen's first announcement sufficient experiments have confirmed the value of his discovery and have pointed toward applications which, though yet unachieved, only await a development of details similar to that which converted Daguerre's slow, faint and uncertain methods into the instantaneous and brilliant photography of the present day.

In brief, Röntgen has found that the electrical current passed through a Ruhmkorff coil and thence to a Crookes' vacuum-tube, develops from the cathode an invisible form of energy, having the double property of penetrating certain ordinarily opaque substances, and of affecting an ordinary photographic plate. Flesh, for instance, is translucent to these rays, and bone and metal, glass and graphite, are comparatively impervious. On this difference in penetrability depends the

effects which are permanently recorded by ordinary photographic plates. Perfect clearness of definition has not yet been attained. It will be convenient to coin the words skiagraph or skotograph to characterize pictures produced by the X-rays and to indicate at once their relationship to and their distinction from photographs.

The surgical imagination can pleasurably lose itself in devising endless applications of this wonderful process. If it becomes possible to drive these mysterious rays through the entire body as clearly as they now penetrate the hand, the realm of utility will be practically boundless. It is stated that stone in the kidney has already been determined, and the opacity of glass has led to the detection of small pieces adherent to bone after accident. The similar opacity of lead may render the probe useless in gunshot wounds, except in rare cases as when the bullet is buried in the bone. A new means of distinguishing luxations from fractures is now added to the long list at our command. Obstetricians will readily perceive the immense value of ability to *see* the fetus in utero after ossification of its bones has occurred. The representation of deformed pelves in the living subject, of spondylolisthesis, of calcareous infiltration of various parts, such as arteries, and of exostosis—all this opens up a tempting and promising field for practical research.

Incredible as all this may seem the original skiagraphs photographically reproduced in the annexed plate will convince the most doubting.

The plate[1] shows a number of objects which I have selected at random. In Fig. 1 is represented a portion of the small intestine containing mucus and fecal matter. In this have been placed a penny, a lead pencil, and a gall-stone. The penny is markedly distinct, the lead of the pencil is plainly visible, while the paint of the pencil, rather than the wood itself, has given the outline seen in the cut. The shadow of the irregular gall-stone can be seen. The photographic plate on which this impression was obtained was wrapped in three thicknesses of paper; and in order to distinguish the film-side of the plate, a mark was made in the centre with a lead pencil, and this is also seen in the figure. Fig. 2 shows a portion of a fresh cirrhotic liver, one centimetre in thickness, in the centre of which a number of pins had been inserted. Fig. 3 represents a rib covered over in its central portion with a section of cirrhotic liver tissue, one centimetre in thickness. The blade of the penknife in Fig. 4 was covered with fresh lung tissue, two and three-quarter centimetres in thickness. It would seem that the closer the object is to the plate, the more successful the exposure. Hence it is that some of the objects which have been taken present an appearance not so distinct as the others.

Fig. 5 shows a hand with polydactylism and webbed fingers.

Fig. 6 an ankylosed bone.

Fig. 7 a bullet and piece of glass in a hand preserved in alcohol.

It may be noted that the skiagraphs herewith presented are the results of preliminary experiments. They will be continued by the writer in the physical laboratory of the University of Pennsylvania, through the kindness and courtesy of Professor Goodspeed, to whom is due the honor of being the first in Philadelphia to repeat Professor Röntgen's experiments. It is confidently hoped that the time of exposure will be shortened and the penetration of the rays increased. It will be comparatively easy to obtain pictures of acromegaly, osteitis deformans, gouty deformities, rheumatoid arthritis, etc. Especial attention will be given to the differentiation between organic and inorganic substances, and between those tissues in the human body which react and those which do not.

The easy application of Röntgen's method of taking a picture on a sensitized plate renders its use at once possible in hospitals. The entire cost of such an apparatus need not exceed $50, and this amount will shortly be materially diminished. Doubtless the scientific and commercial ingenuity now being focussed on this process will soon produce outfits at once simple, convenient, and portable, and it is safe to say that most practitioners will then provide themselves with the means of seeing into the mysterious recesses of the body now accessible only by means of the knife.

ROENTGEN PHOTOGRAPHS AND SOME INTERESTING FEATURES OF THE DISCOVERY.

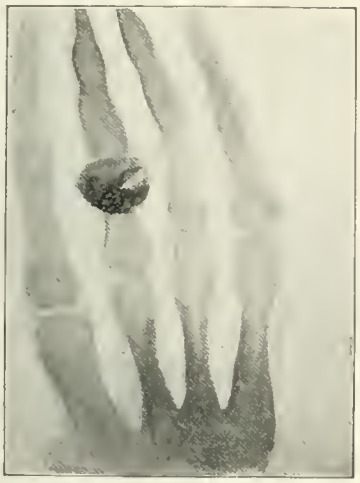
We append herewith two Röntgen photographs taken from *Nature*, January 23d. They are photographs of living hands, and the difference in the two is due simply to the greater intensity of the light. In the first one the flesh of the hand becomes almost invisible, while in the second the contour of the hand and fingers is retained.

In our interest and enthusiasm in this matter, it is well not to lose sight of the fact that there were men who understood this process before Professor Röntgen published his recent article upon the subject. The wonderful penetrating powers of these rays were alreadyknown and had

[1] Opposite page 169

been noted by Hertz, while Lenard, two years ago, had obtained by means of Crookes' tubes shadow photographs similar to those of Röntgen. The feature that is peculiar to Professor Röntgen's discovery and which has so stirred the public interest, and particularly that of the medical profession is that bone is impenetrable to these rays, while the flesh is not, and therefore it is possible to get a shadow picture of the bony structure, not only of the hand, but other parts of the body, by passing these rays through the flesh.

Professor Wright, of Yale, has obtained shadow pictures of the entire skeleton of a rabbit, showing that the rays will pass, not only through the flesh, but also the fur of an animal.



Photograph of the bones in the fingers of a living human hand. The third finger has a ring upon it. [From *Nature*, London.]

Already improvements in method and other discoveries as to the properties of these rays are being made. The opinion of some of the best experimentors is that these rays can be produced in the ordinary electric light bulb. Indeed, the characteristic fluorescence of the cathodal rays has been obtained upon a sensitive plate without the use of Crookes' tube, and it is therefore quite within the realm of possibility that shadow pictures may be obtained in the same way. The length of time necessary to procure a picture by exposure to these rays is also being constantly reduced, from several hours, which was the period originally deemed necessary, to forty, twenty, and even four minutes. The time is doubtless not far off when, as Dr. Cattell has suggested, instantaneous pictures will be taken by this method.

A peculiar feature of these rays is that, although they are capable of producing a brilliant fluorescence by coming in contact with a sensitized plate, they are not visible to the human eye. Even when interposed in the direct path of the rays, the eye is not cognizant of any effect, either of light, or heat, or pain.

We would also call attention to the telegraphic

Photograph of a living human hand. [From *Nature*, London.]

communication in another column of Dr. A. Lapthorn Smith, which probably records the first instance, in this country at least, in which this process has been practically utilized in surgery to locate a bullet lodged in the flesh.—[ED.]

SHALL THE STATE UNDERTAKE TO RESTRICT THE SPREAD OF TUBERCULOSIS?[1]

BY JOHN L. HEFFRON, A.M., M.D.,
OF SYRACUSE, N.Y.;
PROFESSOR OF CLINICAL MEDICINE, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY, ETC., ETC.

FOURTEEN years have passed since Koch announced the discovery that a specific bacillus is the primary cause of tuberculosis, and demon-

[1]Read before the New York State Medical Society, at Albany, N. Y., January 28, 1896.

strated that the disease could be reproduced in susceptible animals. To many careful students who had observed accurately the history of the disease, this announcement came, not as a matter of surprise, but as a confirmation of theoretical conjecture, based on strong reasoning and experimental work with tubercular tissue. These received gladly Koch's communications on the subject, and, in their laboratories, duplicated his methods, reproduced his results, and confirmed the correctness of his deductions. In a short period of time the objection that the characteristic bacillus, admittedly found in all tubercular tissues and in their discharges, was not the cause of the disease, but the incidental accompaniment of it, was silenced by the contemporaneous evidence of experimental observers of all nations.

In a similar way the infectious nature of the virus has been established beyond a peradventure, so that it was long ago proven that tuberculosis is reproduced in susceptible subjects, not only by experimental inoculations, but as readily by the direct inoculation of an unprotected surface by unsought contact with matter containing the specific germ. The investigations of the dust of consumptives' wards in hospitals, of houses in which tubercular patients had dwelt, of churches and theatres and schools and public conveyances which had been frequented and contaminated by those having tuberculosis, have established the fact that the process of drying does not kill the germ, and that after lying dormant for months they are capable of active reproduction, and of initiating the disease of which they are the cause. In the investigation of food supplies from tubercular animals, the same results have been attained, and have been so thoroughly established that our State and many others are now prosecuting a crusade against tubercular domestic animals, for the protection of mankind from this one source of infection.

All these facts have been known to the profession for many years, and for as many years there has been no one to raise a voice against them. Indeed, the younger physicians have been so educated that to them any other possible cause for consumption or for its distribution is known only as a matter of ancient history. But when we search for results springing from this discovery, at all commensurate with its greatness, we are met with disappointment and surprise. By State control leprosy has been banished from civilized nations, smallpox has been robbed of its sting of death, scarlet fever and diphtheria have been limited in their spread, but tuberculosis, with its multiform manifestations, still claims one-fourth of all the deaths for its own. From the forthcoming report for the year, 1895, Dr. Smelzer, the Secretary of the New York State Board of Health, has kindly furnished me these statements:

"The total reported deaths from consumption in our State for 1895 is 13,330. The average reported deaths annually for the past ten years is 12,616." That these statements do not indicate in full the actual deaths from tubercular diseases we all know perfectly well, so that these figures, as appalling as they are, in order to represent the true conditions, must be materially augmented. That such an annual sacrifice of life on the altar of tuberculosis is necessary, not one of us believes.

Modern science teaches that tuberculosis is rarely hereditary, almost always communicated, and, if not preventable, it is at least capable of very great restriction. These ideas are prevalent the world over, and in the most enlightened communities are receiving attention. Our own State Board of Health, though behind others in this respect, has not been unmindful of the importance of this subject. In November, 1894, it formulated a circular letter to be sent to the Health Officers of the State, setting forth the facts here briefly mentioned, requesting the coöperation of physicians in reporting cases of tuberculosis, and suggesting that it might be wise to distribute to those families in which tuberculosis exists information as to how the disease is communicated and what precautions should be observed. Such action is but preliminary, and is not sufficient. Any action on the part of the State Board of Health must have the hearty coöperation of the great body of intelligent physicians, whose representatives are here assembled, and any action to be efficient must be mandatory, not advisory.

From the absolute knowledge in our possession that the infectious material in tuberculosis resides wholly in the secretions from the part affected, it seems possible to restrict the propagation of this disease with more certainty and with less inconvenience to the afflicted and their friends than in any other infectious disease. To secure such restriction, a campaign of education of the people must be inaugurated. The people must be taught the nature of this disease, the methods of its propagation, and the means that must be employed to control it. For this purpose perhaps no plan that has been proposed is superior to that which has been adopted by the State Board of Health of Michigan, and which, in other diseases, has proved

to be of such absolute value for the past twenty years. By this plan it is obligatory upon every physician and every householder to report to the local Health Board every case of tuberculosis. To each patient, and to his friends, and to those who come in contact with him, is sent a circular of information setting forth in simple terms all of the facts concerning the nature, communicability, and necessary preventative measures to be observed to protect himself and his friends from the further spread of the disease.

To secure a universal dissemination of accurate information concerning zymotic diseases, the State of Michigan has within the last year made it obligatory to teach all pupils in the public schools the fundamental facts and practical methods of sanitation in all known infectious diseases. In reply to a letter of inquiry concerning the practical workings of the methods so far adopted, Dr. Baker, Secretary of the State Board of Health of Michigan, says: "Though it is too early to show by statistics the result of this plan, it is noticeable that many people have been set to thinking on this subject, and much interest has been manifested." In one of his able addresses on "Consumption as a Disease Dangerous to Mankind," he states facts "which seem to warrant the hope that the restriction of consumption will prove easier than the restriction of scarlet fever," and on a previous page he has proved by statistics that, since the adoption of this plan in 1874, "The death rate from scarlet fever in Michigan was less than one-half what it had been previous to the beginning of the work."

The campaign of education involves more than the necessary instruction directed to the patient and to his immediate friends, and more than the instruction of the children of this generation. It must extend to all municipalities, to all organizations possessing public halls, to all public passenger carriers, to all architects. A person recently returned from Colorado said: "The streets are fairly slippery from the expectorations of consumptives who are there for their health." We have known a previously healthy person to return from a visit to Colorado with consumption, a symptom of which neither he nor any of his family ever before presented. Dr. Ghion, the late Medical Director of the U. S. Army, said that he was never in such constant fear for his life, not even in the midst of an epidemic of yellow fever, as he was on a journey from New York to Florida by steamer, in a throng of expectorating consumptives going South "for their health." Public buildings must be treated as infected places and cared for as such. Heating and ventilation of such halls must be so carried out as to minimize the possibility of inhalations of dried sputum. Public carriers, like street cars, and steamers, and railroad companies, must be induced to prevent expectoration upon the floor; and such a course is very easy of accomplishment, and far more important to the comfort of the passengers than the regulation of smoking. It is to the credit of some street car companies in certain cities that a prominently-placed placard announces that "Spitting on the floor is not allowed." The inculcation of such instruction, widely disseminated, will make unnecessary the methods employed in some German cities, of placing at convenient intervals on the streets public cuspidors with their unsightly contents. Every one should be taught to protect the public from the discharges from his mouth, as he has been taught from infancy to control the excretions.

That there are difficulties in the way of attaining perfect control of those having tubercular discharges is self-evident. It is to the very fact that the difficulties are so great that the apathy of the profession is to be charged. It may be well to review some of the difficulties that must be surmounted. First of all, what have we, as physicians, to overcome in our own ranks? We are the descendants of our fathers, and have inherited a dislike of telling disagreeable truths. In earlier days, to tell a person he had tuberculosis, or consumption, was equivalent to pronouncing a death sentence. We are not yet free from this thraldom, though we know perfectly well that modern statistics can show a recovery of 50 per cent. of cases detected early. A competent physical examination is often not insisted upon. A bacteriological examination of sputum, in those early cases where little but malaise is complained of, and where physical exploration fails to reveal the first beginnings of the disease process, is very frequently neglected. Often when the symptoms are unmistakable, even to the friends, the doctor yields to the importunities of the family and makes them comfortable by an offhand diagnosis of "bronchial trouble" and omits all hints of danger to any one else. Many object to reporting cases of tuberculosis on the ground that they are unwilling to brand a man as a consumptive and thus blight his life in the community in which he lives. Thus, in our own ranks we must overcome errors that are directly traceable to carelessness and sentimentality.

Among the intelligent people there is little to overcome save pardonable ignorance. Con-

sumption is so very common that the people feel at home with it. It is considered a terrible affliction, but one so often observed that familiarity with it has bred more than pity.

The intelligent people need but this specific education. They need but to know that this fell destroyer is capable of control, that to control it it is but necessary to destroy the virus contained wholly in the discharges from the diseased organ, and the assurance that, in its control, the loved victim need suffer no curtailment of his inherent rights, no diminution of their tender care, and that in a careful observation of sanitary regulations, he is not only protecting them, but is, by so much, making his own cure the more possible. And they need to realize the necessity of an early and accurate diagnosis, and the danger of neglecting the first beginning signs of enfeeblement.

With the ignorant poor, and the wilfully careless and the vicious, the case is not so simple. Because of the greater difficulty in educating these classes, it is a question if it would not be wise at the start to empower health boards to isolate, in specially adapted hospitals, such as will not or cannot conform to the regulations for home care. That certainly will come in time, for, as soon as a public sentiment in favor of the restriction of infectious diseases is firmly established, just so soon will the people force those put in charge of the public health to compel an observance of sanitary laws on the part of the wilful and the ignorant.

If we are profoundly convinced of the possibility of restricting the ravages of this scourge of mankind, shall we escape deserved censure for not making a vigorous effort, because there are difficulties in the way?

No timid, half-hearted, apologetic and advisory action will ever win the coöperation of the profession and the respect of the people. But if the plain facts are vigorously stated, that tuberculosis is a curable disease, a contagious disease, and a preventable disease, and that with the coöperation of the people of the State, every one of whom is vitally interested, the number of cases can be diminished 50 per cent. in ten years—as is firmly believed—I predict that we should have such strong support from the more intelligent of our citizens that the ignorant and the vicious would be speedily compelled to conform to the prescribed sanitary regulations.

To summarize, the following conclusions may be drawn:

1. Tuberculosis is an infectious and curable disease, capable of restriction.

2. That the State should compel the registration of every case of tubercular disease.

3. That circulars of information as to the nature, communicability, and sanitary care of all tubercular disease should be sent to those afflicted with the disease, and to those attending them.

4. That instruction as to the nature of contagious and infectious diseases, and the practical methods for their control should be given to all senior pupils in public grammar schools.

5. That all owners and trustees of places of public entertainment, including churches and schools, and all public carriers should be required to prevent contamination of their halls and conveyances, and to disinfect them when contaminated.

6. That the hopelessly ignorant, wilfully careless and vicious afflicted with tuberculosis should be isolated in special hospitals provided by the State.

THE TREATMENT OF MALIGNANT TUMORS IN SO-CALLED CANCER CURE INSTITUTIONS.[1]

By NATHAN JACOBSON, M.D.,
OF SYRACUSE, N. Y.;
PROFESSOR OF CLINICAL SURGERY, COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY; SURGEON TO ST. JOSEPH'S HOSPITAL, SYRACUSE, N. Y.

It is rather my purpose in this paper to invite a discussion upon the subject of what is claimed for and accomplished in the so-called "cancer cure" institutions, than to enter widely upon its consideration. It is known to all, that people afflicted with what is, or what they are told is malignant disease, seek relief from their afflictions at the hands of these "cancer specialists," both because of their fear of the knife, and the glowing promises made for their certain cure by escharotics. The claims of these cancer hospitals are set forth in very seductive language and the most positive assurance is given that their method, and only their method, can effect a permanent cure.

While not aiming a blow at any single institution—as my intent is rather to discuss methods and results—my attention has been particularly directed to the work done in one of them, and I assume that this work is the type of all.

In the pamphlets issued by this and similar institutions, it is stated in vigorous language, that the knife fails to cure more than ninety-five per cent. of the cases operated; that the only argument in favor of operation upon cancer of the breast, for example, is that it can be done in from one to three hours, and the wound healed in from

[1] Read before the New York State Medical Society, January 28, 1896.

two to four weeks. But in the same breath we are assured that such a procedure is certain to witness a return of the disease in worse form, and that the arm on the diseased side is sure to be impaired and in many instances rendered entirely useless.

It is further stated that the entire profession recognizes the inability of the knife to remove the disease, and hence recommends operation, only as a last resort. Moreover, the most serious objection to removal of the breast by operative measures, we are told, is that the surgeon is unable to determine, be he ever so skillful, whether or not he has removed the last vestige of the disease, while the escharotic method entirely circumscribes the mass, protects the healthy parts from further invasion, and when the slough has separated there remains a granulating wound so absolutely bloodless that one is enabled to determine what portion, if any, of the disease still remains. We are further informed that if any cancer cells exist, they positively stare you in the face, and that they can be at once removed by this same method. It appears furthermore, that the particular remedies applied are of secondary importance, and that the value of the treatment lies in this ability to determine whether or not the disease has been removed, and only their particular method renders this possible.

The claim is further set up that no other known method is as painless, and produces so little inconvenience; that the pain is never severe enough to prevent sleep, nor to confine the individual to her room.

It is asserted by one of these institutions, that up to the present time, there never has been a failure to effect a permanent cure in any case in which their physicians were able to give a favorable opinion. To use their own statement, "We can truthfully say, that we never fail to cure any case of cancer, where we have had and accepted the first opportunity for treatment," and this is from the institution of which we will hear more in detail. In a circular at hand, we learn that more than three-quarters of all physicians and surgeons in good standing in the United States, indorse their method. The serious charge is made that the surgeon is aware of his inability to cure this disease, and that for mere pecuniary gain and absolutely for no other reason, he performs an operation, knowing full well that it cannot prolong life, but in reality shortens it, as the disease is certain to progress more rapidly after than before operation.

What these "cancer specialists" designate as cancer and treat as such, is perhaps summarized best in one of their published statements, which I quote verbatim: "Nearly all those lumps and kernels that appear on or in the breast, and all those sores, lumps, or unnatural appearances in the form of crusts, warty excrescences, which occur in either sex, but far more commonly in the male, on the lip, nose, eyelids, face or any part of the surface, are cancers, and should have immediate attention. The only symptoms for months, and in many cases for years, are occasionally a stinging, shooting, burning, itching or creeping sensation, and in many cases not even any of these. If you have a branny, scaly, crusty or warty appearance, with an occasional exfoliation of the same upon the face, lip, nose, or any other portion of the skin, attended with any of the above symptoms, or giving an occasional sensation as though a fly had alighted upon the part, or a hair were tickling it, the evidence should be conclusive that your trouble is cancer, and no delay should be made in having it cured. Life is far too valuable to be tampered with or sacrificed."

We are assured that the time required for the cure of these cases by escharotics is quite brief. The enticing statement is made in a pamphlet issued by an institution, whose work I shall presently analyze, that by recent improvements in their method, they are enabled to shorten the stay of their patients, so that for cancer of the breast, even though extensive, three to five weeks suffices, and in the less severe cases the period is proportionately shorter. In another institution, as low a period as two weeks is given. Each case, however, can be and is told approximately, how long a time will be required to effect a cure, after the preliminary examination has been made.

Unfortunately, many of these institutions are in the hands, not of ignorant, uneducated pretenders, but men who have been liberally educated in the arts and are graduates of recognized medical schools.

My attention was particularly called to this subject by the treatment a lady who had previously been under my care received in what is claimed to be the largest and most successful of the sanitariums for the cure of cancer in the United States. Certain it is, this institution in the printed circulars it issues, makes the most extravagant representations as to the simplicity, painlessness, brevity, and efficiency of the treatment.

To place in bold relief, however, the actual condition of things as opposed to the false and untenable positions taken by the so-called "can-

cer specialists," allow me to present to you not only the history of this patient, but also what was unearthed during her stay in this cancer hospital.

Mrs. A. consulted me November, 1891, when I found present in the outer upper quadrant of her left breast a movable, hard, nodular tumor, which presented the usual appearances of scirrhus. I urged amputation of the breast. She was fearful of the knife and would not consent. For a year I had her under observation, during which time the growth made very slow progress, remaining freely movable, excepting as it grew toward the surface, where it became quite adherent to the skin. However, it could be entirely circumscribed, and at no point was it attached to the chest wall. There were no glandular enlargements recognizable in the axilla. The continued presence of the tumor and the diagnosis given naturally alarmed her, and without seeking further medical advice, she placed herself in a widely known "cancer institution."

She entered it September 19, 1893, and was assured that her case was a promising one and that a cure was certain. Fourteen months of treatment—I might more truthfully say of torture—were spent here. Her husband states that the first application was made at 10 o'clock in the morning, and that until 4.30 in the afternoon she was almost wild. The application was repeated on three consecutive days, and afterward every three to four weeks, during the period of her stay. Widespread sloughing resulted. She became steadily more emaciated and enfeebled until, on the 10th of October, 1894, she was obliged to take to her bed, and then was told she had pneumonia. On the night of November 5, 1894, she was carried out of the "sanitarium," placed upon a train, and transported home. On leaving the institution, her medical attendants declared that there was no trace of the malignant disease left, that she was entirely clear of every vestige of cancer.

I saw her on November 11, 1894. Her pulse was so feeble that I could scarcely feel it; the respirations were 24 and the temperature 99.

At the previous site of the left breast, instead of a mamma, there was extensive scar tissue. Midway between the mammary and axillary lines, on a level with the third rib, there was an unhealed area. This side of the chest presented patches of dullness. There were no râles and but a small amount of air entered the lung. The entire right lung was likewise infiltrated, presented no râles, but only admitted a small amount of air. From this date she gradually failed until she faded out, December 14, 1894.

After death, as she was placed in the recumbent posture, a position she could not fully assume during life, a large amount of serum poured out of the chest, through the unhealed area on the left side which opened directly through the chest wall into the left pleural cavity. Pleural adhesions existed on all sides. Each pleural cavity contained serum. The left lung was filled with small secondary deposits, but at no place was there direct extension inward, from the surface, nor was there any involvment of the ribs. The right lung was very much contracted, solidified here and there, and saturated with secondary growths, varying from one-half to three-quarters of an inch in size. The heart wall was thin and flabby. There was no evidence of secondary involvement of any other organ.

While at the institution, her husband had been her constant attendant. He became well acquainted with the various inmates, and as a matter of personal interest, formulated a table which records the names of all the inmates of the institution, at the date of admission of his wife, *i.e.*, September 19, 1893. His table notes the residence, the respective age, sex, date of admission and dismissal of the various patients, the site at which the disease was located and the ultimate termination of the various cases.

Let me present to you these statistics. Whether they are better or worse than we could obtain from the same institution at other times, or whether this tabulated statement tells the full truth for all time, I cannot say. Certain it is that these "cancer specialists" do not publish their statistics and that it is rarely we can ever obtain exact information concerning them.

To avoid any legal entanglement, as I am not desirous of courting a lawsuit, I do not mention the name of the institution. I can assure you, however, that my statistics are absolutely trustworthy and that they are presented as furnished me.

It appears that there were twenty-six patients in the "hospital" September 19, 1893. These are classified in four groups. The first contains ten cases of cancer of the breast and includes my patient. All of these had been subjected to the treatment and each one of the others was dead when my patient passed away, December 14, 1894. One of these after a period of treatment of five and a half months died in the institution. Another lived ten days after her dismissal; still another died in four weeks, my patient in six weeks, and yet another in two months. None lived longer than nine months. One of these was under treatment in this institution for a period of one and a half months, one four and a half, one five and a half, and the remainder from nine to fourteen months, with an average of eight months for the ten.

In the next group are placed six cases who were under treatment for periods of five months, seven and a half months, eleven, twelve and fourteen months, respectively, with an average of ten months, and who after this prolonged period of torture were finally pronounced hopeless and sent home to die. How many of these are dead I cannot state, inasmuch as their cases have not been followed up. In this class the breast was involved twice, the uterus once, and likewise once, each, the eyelid, lip and face.

In the third series were eight cases indicated as not having recovered. Of these, four were of the breast and four were epithelioma of the face, one being described as being the size of a "hazelnut," the second of a "bean," the third as "trifling," and the fourth involving the face and nose, and is marked as having again developed. The latter, therefore, should not be included in this group, nor should one of the breast cancers, which also has given evidence of return.

The two remaining cases are classified as doubtful, inasmuch as there was fear of recurrence of one where the breast was involved, the treatment having been prolonged for a period of eight months, and the second one marked as a slight case affecting the nose, she having been an inmate of the institution for four and a half months.

To summarize then: Of the twenty-six patients, ten were dead at the time the cases were tabulated, six were pronounced hopeless, three more had the cancer recur and seven believed themselves to be cured. Among the latter, four certainly were very trifling affairs. Whether all of these were positively cancerous, there is grave question, and whether all so indicated and not heard from have remained free from recurrence I cannot state. But were we to concede that they all were cancers and that none had recurred, the results still make a frightfully bad showing.

When we compare these results with the fair promises held out by these institutions of the certainty of cure, where the patients are accepted for treatment and assured that their cases are favorable for escharotic treatment, it becomes at once apparent what an awful misrepresentation these institutions make and how great the imposition is.

The statement, as you will recollect, is made by them that the regular profession resort to the knife simply for pecuniary gain. The husband of my patient informs me that he paid $50 per week for the so-called treatment of his wife during the entire period of fourteen months, and this included neither her board nor room, but was simply for the so-called "professional visits" of

PATIENTS UNDER TREATMENT, SEPTEMBER 19, 1893.

her medical attendants. In short, for the "professional treatment," exclusive of all other necessary expenditures in this case, the fees amounted to $3,000.

I am informed that one of the patients in the second group, a man of very limited means, and whose home was in California, was promised a cure with two months treatment. After fourteen months the poor man turned over all the money he had except barely enough to carry him home, with the cancer of the face not only uncured, but much worse than when he entered.

It is unnecessary for me to state to this society how untruthful the charges against our profession are, how absolutely false is the statement that 95 per cent. of cancers treated by the knife do not recover; that it is impossible to reach beyond the disease with the knife in a case where it can be circumscribed; that the prospect is less favorable by operative procedure, and that, in short, all of the claims made by these so-called "cancer specialists" are absolutely unwarranted.

I have not discussed the subject from the standpoint of pretended cures for cancer when the patient has only been afflicted with an innocent tumor. That many of the so-called cures are of this kind, there can be no doubt. This is apparent in the statement quoted which defines malignant disease from the standpoint of these "cancer specialists." To make the table yield the best possible returns for them, I have conceded that all of their cases were cancer. The results are horrible enough at best.

I have inserted the table, which I believe will bear careful study.

SOME PRACTICAL POINTS CONCERNING URINALYSIS IN DIAGNOSIS. THE PART OF URIC ACID IN CERTAIN DISEASES.[1]

By G. J. TWEEDY, M.D.,
WINONA, MINN.

There are two theories as to the part played by the kidney in the formation of urine. The first is that of Ludwig, according to which the process is a purely physical one—partly a filtration and partly a diffusion or osmosis. The blood pressure being increased in the Malpighian tufts, the watery portion of the blood together with some dissolved salts escapes into the Malpighian capsule. In this way the blood is very much thickened by the time it reaches the second capillary network embracing the convoluted tubules, into which has descended the thin aqueous solution from the capsule. Here the thin wall of the blood vessel together with the delicate membrane of the tubule, forms a perfect osmometer, with the dense blood on one side and the thin saline solution on the other. An interchange now takes place, by which a current of liquid sets in from the tubule to the blood, and of the products of regressive metamorphosis, urea and salts, to the tubules, concentrating the fluid in the latter, and making urine of it. The researches of Heidenhain since that time have shown, that in addition to this the convoluted tubules and looped tubes of Henle are concerned in its elaboration. It is, however, regarded as established, that the chief materials of the urine, with the exception of hippuric acid, preëxist as such in the blood and are therefore merely removed by the kidney. Normal urine should be a transparent aqueous fluid of a pale lemon color, varying somewhat according to the amount of liquids ingested and the activity of the skin.

A few minutes after being passed there is usually a faint cloud of mucus derived from the genito-urinary tract. In females this cloud is apt to be more marked, in consequence of a large amount of epithelium from vagina and vulva.

The reaction of healthy mixed urine, *i. e.*, of twenty-four hours, is always acid; a few hours after a meal it may become neutral or alkaline. The cause of this change in reaction is still disputed, Roberts believing that it is due to an admixture of the blood with the elements of food, which is largely alkaline, Bence Jones contending that it is caused by the large amount of acid gastric juice which has been extracted from the blood during digestion; probably both enter into the causation.

Normal specific gravity is about 1020. When from the action of cold or other cause the skin is not acting, and after copious use of water or diuretics, it may descend to 1010 within the limits of health; but when perspiration is copious or a drain of water takes place from some other channel, the urine becomes concentrated, and may be 1030 or higher. The specific gravity is also increased in the first stage of acute fevers, in consequence of the increased amount of solid matters excreted, in the first stages of acute Bright's disease, from the presence of blood, in diabetes mellitus, from sugar. It is diminished in hysteria, in all forms of Bright's disease except the stage of acute nephritis referred to, and in the condition known as cyanotic induration of the kidney, which often attends heart disease. In a general way, the presence of sugar and albumin being eliminated, variations in the specific gravity

[1] Read before the Winona County Medical Society, January 7, 1896.

point to variations in the amount of urea present; lower specific gravity of mixed urine generally means less urea. Normal quantity may be set at about fifty ounces per day.

Now let us consider the nitrogenous products of tissue change found in urine. A great many of these are found in the blood, and but few in the urine. Cholesterin is but rarely found, and is not worth considering here. Leucin and tyrosin are found only in acute yellow atrophy of the liver, in phosphorus poisoning and in rare cases of smallpox, and on this account these crystals may be said to be almost pathognomonic. But by far the most important of this group is uric acid. The term, uric acid, will include all its combinations, urates of soda, ammonium, calcium and magnesium.

Uric acid, like urea, is a product of tissue change, and is increased by: first, excess of nitrogenous ingesta ; second, most febrile conditions where tissue change is going on rapidly ; third, in most wasting diseases, *e. g.* phthisis ; fourth, in diabetes.

It may be decreased by: first, certain diseases of the liver ; second, fasting ; third, vegetable diet—its place being occupied altogether by hippuric acid in the herbivora.

Of much more importance, however, than its formation is its excretion. Roberts says : "It may be regarded as probable that the defective power of the kidney to eliminate uric acid in gout arises from a diminished alkalescence of the blood ;" or, in other words, the uric acid is not in solution in the blood, and is never brought to the kidneys to be excreted ; because uric acid is not soluble in a neutral solution, a slightly alkaline one, or an acid one. It follows on that account, that foods or drugs which render the blood more alkaline have more uric acid in solution, more is brought to the kidneys and more excreted.

The question would then naturally arise. On diminished alkalescence of blood, what becomes of the uric acid ? Sir A. Garrod says, it is attracted differently by different organs, and thus the spleen and liver more frequently contain appreciable quantities than other organs, and further on, "may it not be, that, in some organs as the spleen, the substance of which, if not acid during life, rapidly becomes so after death, while the blood remains strongly alkaline, the uric acid becomes less soluble and more easily retained." Therefore on the administration of a dose of acid, the liver and spleen become more acid and cause increased retention of uric acid in them, while a dose of alkali will diminish their acidity and sweep out the uric acid retained there.

Now I shall endeavor to show how this theory explains a number of pathological conditions. First, headaches. Allan McLane Hamilton says: "An experience of many years has taught me that uric acid poisoning is at the bottom of many functional nervous diseases as well as some organic ones. Many individuals of the gouty habit, without actual classical gout, but with a thousand and one erratic symptoms, are the subjects of headaches, which rapidly disappear when a proper alteration of habits and food is made, and when they are placed upon remedies of a suitable nature. The subjects of such headaches are often men, and more usually those past middle life, though the headache of uric acid is confined to no particular age." If we take a typical case of uric acid headache, we will usually find it to begin shortly after breakfast, continue all day with some variations in severity, and at night usually disappear. This corresponds to the time when uric acid is circulating freely in the blood. It comes on after several days of well being, wherein the patient has had a good appetite and partaken freely of meat, and has also had considerable exercise, both bodily and mentally. We now find that the commencement of the attack corresponds to the period of most marked alkalinity of the blood; this alkaline tide sweeping out the uric acid from liver and spleen, which has been stored up during the acid tide period of sleep (if I may be so allowed to call it), and which now acts as an irritant. This irritation causes contraction of blood vessels throughout the entire body; it is not unlikely then that it may produce spasm of blood vessels in certain vascular areas, especially in the pericranium, which is the accepted theory of migraine. This will readily explain the morning headache due to excesses in wine and beer the previous night.

Sir A. Garrod, in speaking of acidity, says that fresh fruits diminish acidity through conversion of their vegetable salts into carbonates; and this, I think, gives us the key to the whole matter. Wines, ales and beer may all be regarded as solutions containing a very small amount of albuminoids, a certain amount of alkaline salts and a certain amount of acid, either free or combined; and it is obvious that if the alkalies or the vegetable salts which can be converted into alkaline carbonates predominate, the beverages will act as doses of alkali, while if the acid and acid salts, incapable of conversion, predominate, they will act as doses of acid, and we get the uric acid precipitated and

retained until the blood is rendered more alkaline, and thus, from the excess in the circulation, we get headaches.

I have under observation at present a man who has suffered with headaches at intervals of two or three weeks for a good many years, and on my explaining this theory to him he readily agreed to some little experiments, and we found that by having him eat freely of meat for several days, and at the same time drink acid drinks, the urine became very acid and the uric acid in it diminished; then, upon giving him a large dose or two of bicarbonate of potash, he promptly got a headache, with increased excretion of uric acid, and this headache could again be promptly stopped by giving half dram doses of dilute nitrohydrochloric acid, showing very clearly that in the first place the acid was retained and then rapidly excreted under the potash, and again retained on giving the acid. A singular thing, too, is that an acid will not only prevent or cure a headache of this kind for a day or two, but for weeks. The most rational explanation of it is that the retained uric acid becomes converted into urea; and the fact that uric acid given by the mouth does not increase the amount in the urine might be regarded as evidence of uric acid being thus convertible. Indigestion and headaches are sometimes intimately related. Suppose, then, the uric acid present: it either directly irritates or by other means interferes with the circulation in the liver and spleen, in this way bringing about congestion of these organs and catarrh of the stomach, with indigestion, following this nausea and diminished appetite; then later on comes the fall in acidity with plus excretion of uric acid and headache. Closely related to headaches is that "tired feeling," a feeling of mental depression, coming on in the first warm days of Spring, when blood "purifiers" are so much in demand. Examine the urine of those patients and you find it loaded with uric acid, and this is what causes the depression. During the cold months of winter there is usually a large ingesta of meat and a very inactive condition of the skin; consequently the blood is liable to lessened alkalinity and consequent deposit of uric acid. In the first warm weather the skin becomes more active, there is a large loss of the acid portion of the blood from that channel and the blood becomes more alkaline, washing out from the liver and spleen the stored up uric acid.

As to gout, all are agreed that it is merely the result of uric acid driven into the joints.

Sir A. Garrod has pointed out that the cartilages and ligaments of joints are less alkaline than the blood and tissue fluids in general, so that if uric acid is retained in the spleen and liver because they are less alkaline than other organs and tissues, it may be retained in the fibrous tissues and cartilages of joints for a similar reason. Further, the joint structures are less vascular than the liver and spleen, and will be but slowly influenced by blood changes. The most common way in which uric acid comes to be driven out of the blood and deposited in the joints, is by a rise of acidity, but any drug which diminishes the solubility of uric acid, *e. g.* lead and iron, will act in the same way; so that gout is simply a retention of uric acid in a joint, and the cure of that attack is simply a washing out of the urid acid by salicylates, alkalies or colchicum, which latter Broadbent thinks acts as an alkali.

There are two classes of people who usually have gout; the rich, overfed and under exercised, and a certain class of men who work in the water about wharves and docks. This latter class illustrate the theory laid down very nicely. They are constantly drinking cheap beer, which is strongly acid, and their clothing, constantly wet, checks excretion of acid perspiration. Result—deposited uric acid.

Closely allied to gout is acute rheumatism. Flint, in his *Practice of Medicine*, says: "There is a growing belief that acute rheumatism belongs to the class of infectious diseases, and is caused by the presence of a specific micro-organism. The course of the symptoms of the disease can be better explained upon this supposition than upon any other which has been suggested." Gout is due to uric acid and is cured by sal. of soda, with an enormous excretion of uric acid. Rheumatism is cured by sal. of soda, also with an enormous excretion of uric acid. Besides salicylates the only drugs which have obtained any great repute in the treatment of acute rheumatism are the alkalies, and these again promote a free excretion of uric acid. Then again, exposure to cold and wet in a young person will produce acute rheumatism; in an older one gout. Meat, beer and wines are harmful in rheumatism, also in gout. Again, nature if left to herself, generally tries to right matters in any pathological condition. And in this particular case her first endeavors are to render the blood more alkaline and the excretion of uric acid greater by pouring out a strongly acid perspiration. In the face of this it is difficult to see why a microbe should be necessary to explain the symptoms of rheumatism and not of gout.

It is pretty generally conceded that migraine is due to a tetanus in the muscular walls of the vessels of the affected part of the head, and if this be so, and some cases of epilepsy are due to spasm in certain other neighboring regions, and if the spasm in the case of the headache is due to uric acid, it is but a small step to suppose that the epileptic spasm may be due to the same cause. Now, from experiments by different observers, we find, that before an attack of epilepsy the amount of uric acid is very much diminished, while during the attack it is secreted freely, showing that while it is stored up it causes no trouble, but when it begins to circulate freely we get the attack. I do not mean to say that all epileptic attacks are due to uric acid, but I think some are, or rather to its effects on the arterial tension and cerebral circulation, and I think also, where there is an organic cause, such as a thickened membrane or a depressed fragment of bone, which is constantly present, and the attacks occur only occasionally, that these attacks may be precipitated by the vascular changes brought about by the uric acid.

I shall not go into the action of uric acid in the causation of diabetes and Bright's disease, as I hope on a future occasion to have an opportunity of discussing these diseases in the other half of this paper; but we have all noticed that a large percentage of our public men in recent years have died of one or other of these diseases. These men, generally speaking, were high livers, and we may presume did not take a great deal of physical exercise, and as a result had a good deal of uric acid in their blood. This had to be excreted and an irritation of the kidneys may have been set up by it, but this would not account for the presence of a foreign albumin in the blood, and Semmola, of Naples, is authority for the statement that such an albumin does exist in Bright's disease. He also states that an albuminuria may be produced among other things by deficient activity of the respiratory and metabolic functions of the skin, and uric acid, when it causes high tension, contraction of the peripheral arterioles and coldness of the skin and extremities, brings about just those conditions which will interfere with proper activity of skin function; it will thus produce albuminuria, and the albuminuria will eventually produce nephritis.

The relationship of glycosuria to gout has long been noticed, and it has long been observed that they alternate; when the gout is bad the sugar is absent, and when the attack of gout is passed the sugar returns.

Now, in speaking of gout, we arrived at the conclusion that during the attack the uric acid was in the joints. Consequently it was not in circulation, and therefore did not set up the irritation necessary to produce the glycosuria, and after the attack had passed or been treated for some time, it was in circulation and did cause glycosuria. Just once more: Dr. F. Staples a short while ago mentioned to me the fact that he had observed a close relationship between uric acid and asthma, and instanced some cases. I find a scant literature on that subject, but its well known action on the arterioles, either directly or indirectly, will undoubtedly cause asthma in a case thus predisposed.

It follows from what has been said that the best treatment of these diseases is to diminish the formation of uric acid, urea and acids, as far as is compatible with healthy function, and to use some means of diminishing acidity, so that nothing should interfere with the free excretion of all uric acid formed.

These indications are best fulfilled by reducing very greatly the animal food, eating largely of fruit and vegetables and avoiding beer and wine. Exercise, although it increases the amount of uric acid, does not raise acidity, and, indeed, may even lower it. So that it promotes rather than hinders the excretion of all uric acid formed. Drugs are useful at a crisis and to prevent the continuance of severe symptoms, but the only treatment that goes to the root of the matter is prevention by diet. Of the drugs that promote excretion salicylate of soda stands first. It combines with the uric acid and forms the highly soluble salicyluric acid. Next in order come the potash salts, but contrary to my early teaching I find that lithium is of no value whatever in these cases, but really does harm. No doubt the urate of lithium is very soluble, but lithium does not get a chance to combine with the uric acid to form urate of lithium. Given internally it forms a nearly insoluble triple phosphate with phosphate of soda or with the triple phosphates of ammonia and soda; it thus practically removes from the blood one of the well known solvents of uric acid which is generally present there.

A BILL to abolish the office of Coroner in New York State in accordance with the provisions of the new constitution, and the suggestions of the State Medical Society has been drawn and will soon be introduced in the Legislature. Its aim is to restore to the legal system of the State the judicial functions now exercised by the Coroner and to make the examiners purely medical officers. Coroner's juries will consequently be abolished.

THE SYMPTOMS AND DIAGNOSIS OF THE INDIGESTION OF STARCHY FOODS.[1]

By REYNOLD W. WILCOX, M.D., LL.D.,
OF NEW YORK, N. Y.
PROFESSOR OF CLINICAL MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING PHYSICIAN TO ST. MARK'S HOSPITAL.

There are many reasons why the text-books are silent upon the subject of this paper. The ease with which the contents of the stomach can be examined, the accuracy with which the effect of pepsin can be estimated, the zeal and energy of the manufacturers of digestive ferments have placed our knowledge of gastric digestion in a very satisfactory condition. To one who will carefully study the accurate work of Hayem and Winter, and who will follow their teachings, the chemistry and physiology of the gastric fluids are well understood. Yet, after all, the gastric may be stated to be only the preliminary to duodenal digestion. And that gastric digestion is not even essential, is shown by observations of Czerny, who demonstrated that a dog could live for five months after his stomach had been removed.

The digestion of starches, it is well known, takes place in the mouth and in the intestine. The older physiologists were of the opinion that the digestion of starches came to an end in the stomach. Kellogg, however, has shown conclusively that starch digestion can go on, under certain conditions, in the stomach. One hundred and forty-nine cases in which starch digestion was especially studied, complete conversion was found in 2 per cent. The conditions under which this is brought about will be considered at a later period.

Starch digestion, according to Brown and Heron, may be represented as follows:

One molecule of gelatinous is converted into *n* molecules of soluble starch.

One molecule of soluble starch—

$$10\,(C_{12}H_{20}O_{10}) + 8(H_2O) = 1.\ 9\,(C_{12}H_{20}O_{10}) + (C_{12}H_{22}O_{11}).$$ Erythro-dextrin. Maltose.

$$= 2.\ 8\,(C_{12}H_{20}O_{10}) + 2\,(C_{12}H_{22}O_{11}).$$ Erythro-dextrin. Maltose.

$$= 3.\ 7\,(C_{12}H_{20}O_{10}) + 3\,(C_{12}H_{22}O_{11}).$$ Achroo-dextrin. Maltose.

And so on, the resultant being:

$$= 8\,(C_{12}H_{22}O_{11}) + 2(C_{12}H_{20}O_{10}).$$ Maltose. Achroo-dextrin.

We will now consider this digestion as it takes place at the various portions in the alimentary canal.

The term buccal dyspepsia has been used for more than a score of years. It was supposed to be characterized by insufficient nutrition, resulting in emaciation, abdominal distention, flatulence, and colicky pains, or abdominal distress, and was due to imperfect conversion of the starches in the mouth. Investigation subsequently showed that this imperfect conversion was but a part, and perhaps a minor part, of the causation, the more important being hasty mastication. The hasty mastication resulted in (1) imperfect breaking up of the starch grains, (2) deficient quantity of saliva, and (3) imperfect insalivation. Since the conversion of insoluble starch into soluble sugar depends upon not only a sufficient amount of saliva, but also upon trituration of the starch grains so that their capsules shall be thoroughly ruptured, and thorough mixture of the saliva with the starch, it can readily be seen how very important is complete mastication. With these three factors in full play, starch conversion is practically instantaneous. Naturally a considerable portion in this form of indigestion—so-called buccal dyspepsia—can be cured by eating more slowly, on the one hand, and by limitation of the starchy foods which are ingested, on the other. This cause of dyspepsia is far more frequent than it is popularly supposed to be, and the neglect to properly appreciate this etiological factor explains some of the failures in therapeutics of those who place great reliance upon the results of the examination of the stomach contents. The careless hurrying of the carbohydrates into the stomach without their being properly acted upon by the ptyalin of the secretions of the mouth is, as I have said before, a very important cause of dyspepsia. Lees has recently called attention to another prevalent error, which is frequently, I imagine, even encouraged by physicians. Too much amylaceous food is taken into the stomach soaked in tea, coffee, milk, beef tea, and other fluids. The result of this is that insalivation is not at all performed, and the ptyalin, quite likely deficient in amount from lack of mastication, is present in such small percentage that it is practically inoperative. The stomach is not expected to originate the digestion of starches; it may, and likely does, continue the process, when commenced in the mouth, for about half an hour. The natural inference from this is that fluids of any kind should not be used while masticating amylaceous food, and the patient should be restricted from the too free use of tea, soups with vegetables, puddings with milk or cream, or boiled farinaceous foods with the same. The results which are obtained in practice tend to show the correctness of the observation. When

[1] Read before the Medical Society of the State of New York, at its ninetieth annual session, January 29, 1896.

we consider that, depending upon the dryness and hardness of the food, from one to three pints of saliva are secreted daily, and that the percentage of ptyalin present (in mixed saliva) is according to Frerichs, .0141, the action of the hydrolytic ferment is by no means insignificant. When, from the causes above mentioned, the amount of carbohydrate food daily ingested, which is necessary for an adult, varying, according to Parkes, from twelve ounces (at rest) to sixteen or eighteen ounces in laborious occupation (practically about two-thirds of the total food), is hurried into the stomach with but little conversion, the results to be expected in the intestines are not far to seek. What the effect of the presence of a large amount of unconverted starch in the stomach may be on gastric digestion, is not, so far as I know, determined, nor, indeed, is it within the scope of this present investigation to inquire.

In the stomach it is admitted that the action of the amylolytic ferment, ptyalin, may continue for about half an hour, its activity being finally checked by the fatty acids, or by the free hydrochloric acid, the latter even if in small quantity. On the other hand, it has been stated that when these acids are in organic combination they may favor starch conversion. Recognizing the amylolytic changes by means of the iodine-iodide test (Lugol's solution; starch, blue coloration; erythro-dextrin, red or purple; achroo-dextrin, brownish; the sugar, maltose or glucose, being detected by Fehling's solution) Kellogg found in the series of cases above mentioned that the purple color of erythro-dextrin was detected in 67.8 per cent., and the brown color of achroodextrin in 17.4 per cent. The conditions under which this unusual digestion takes place are pronounced hypopepsia, or to be more accurate, hypopepsia with hypo-acidity. In fact, the state of starch digestion may be a very good index of the degree of total acidity. When Lugol's solution gives a brown coloration or no reaction whatever, complete conversion of starch has taken place and the presence of sugar can be confirmed by the strong reaction given by Fehling's solution. A suggestion may be entertained that the prompt conversion of the starch into sugar which takes place under these conditions may result in the rapid absorption of the digested starch so that the conditions are less favorable for the development of acid fermentation than in the presence of a large quantity of unconverted starch. With this observation by Kellogg, I leave the subject of starch conversion in the stomach.

The digestion of starches is resumed in the small intestine. Owing to the inherent difficulties of the subject the various processes have not been so thoroughly worked out. As a matter of fact, buccal and gastric digestion are merely preparatory to the intestinal. In addition, here, proteids and fats as well as starches are digested, and failure in one direction must necessarily result in abnormalities in the other. In 1890 Boas attempted to study experimentally intestinal digestion in man. For this purpose he made use of vomited matter obtained by a reflux of the intestinal fluids into the stomach. He also made use of the stomach tube and of aspiration. Naturally the irritation of the stomach tube, even if the stomach had been previously irrigated, would result in some gastric fluid, so that unmixed intestinal fluid cannot be obtained. The subject was experimented with while fasting, and the reflux from the intestines was favored by his decubitus and by massage of the epigastric region. Although this method is not applicable to the study of intestinal dyspepsia in our patients, yet the observations of Boas had a certain practical value in that they demonstrated the influence of bad gastric upon the intestinal digestion. Perhaps the sole result of these experiments, so far as concerns starch digestion, is the statement that patients suffering from *hypochlorhydric* do not suffer from intestinal troubles; in other words this is confirmatory of Kellogg's work, which shows that under these conditions starch is digested in the stomach, and the opportunity for intestinal disturbance from undigested starch is not presented. Another factor of importance in intestinal digestion is the presence of micro-organisms, whereas normal gastric digestion is probably free from them. The conditions favorable to the action of amylopsin are similar to those favorable to the action of ptyalin; namely, moderate heat, a slightly alkaline medium and removal of the changed material from time to time. The ferment in the pancreatic juice, distinctly amylolytic (amylopsin), cannot be distinguished from ptyalin. The digestion of starches results in maltose or glucose, the latter being always the final result. Obviously here we must consider that the effect of the pancreatic fluid on starch may be practically inhibited by the discharge of a large amount of acid fluid through a patulous pyloric orifice in cases of marked gastric acidity —another point at which gastric and intestinal indigestion approach. The *succus entericus* from Lieberkühn's glands is believed to convert starch into sugar, but under what conditions and to what

extent physiological literature is generally silent.

So far as the difference in the digestion of starches at the various points is concerned we may follow Kirke in stating that while the pancreatic and intestinal juices are able to turn the achroodextrin which remains into maltose, and maltose into glucose (dextrose) it is doubtful whether saliva posseses the same power.

The difficulty of reaching the diagnosis of the indigestion of starches in the intestine is already apparent, yet we believe that in a given number of instances it can be arrived at with reasonable certainty. The importance of making this investigation is great when we consider that to the assimilation of changed starch we owe much. On the other hand we have proof—if proof were lacking—that the indigestion of starches is a frequent condition—not so frequent, however, as Coutaret in 1870 would have us believe, 60 per cent. of dyspeptics—by the prevalence and somewhat good repute of dyspepsia-cures based on raw beef and hot water. And when we consider that in France bread has a prominent post on the dietary and in other European countries starchy foods are even more largely employed, the importance of the subject is apparent. In this country, not only does hasty eating, but bad cooking, and the imperfectly raised biscuit and cakes, and other pastry are often saturated with greasy substances, and give us reason to believe that starchy dyspepsia is even more frequent.

Taking up the symptoms of intestinal indigestion as referable to the failure of starch conversion I would place first and foremost constipation, of which the cause is quite likely that the colloid-like unconverted starch does not so readily permit of watery osmosis into the intestine as does the sugar into which it is converted, which acts as a crystalloid. The accumulation of undigested and unabsorbed material may even be considerable and give rise to marked enteroptosis (Glenard). On the other hand diarrhea is comparatively infrequent; however, fermentation may go on briskly so that a large amount of irritating material may be formed and its expulsion take place. Should diarrhea exist it is likely to be diarrhea alternating with constipation and not the persistent one which may characterize other intestinal conditions.

The symptom next in importance is undoubtedly flatulence, especially that which occurs two or three hours after meals. The question here arises as to how much of this may be due to gases from the imperfect digestion of proteids in the alimentary canal. To clear up the question we must refer to the work which has been done upon various sulphur compounds. Baumann in 1880 propounded the theory that the combined or ethereal sulphates found in the urine were an index of the amount of putrefactive products absorbed from the intestine; these are chiefly indol, phenol and skatol; the latter is practically of no importance in this study since it is found almost exclusively in the large intestines (Filati). Indol by oxidation become potassium indoxyl-sulphate, long known as indican. Looking upon indol as the product of bacteria upon the proteids as Kuhne and Nencki would have us believe, and considering with this the view of Pisenti that the amount of indican depends largely upon the activity of the pancreatic fluid we come close to the clinical fact that clay-colored stools, excessive preformed sulphates, and abundant indican in the urine are associated with defective secretion of pancreatic fluid. To Herter and Smith all who study this subject must acknowledge their indebtedness for their exhaustive work upon the preformed sulphates and indican and their relations with intestinal indigestion. Since then we have the proteids as the source of sulphur compounds, the causation of flatulence can be determined by the increased ratio of preformed to inorganic sulphates and by the excess of indican in the urine. Therefore, flatulence as a symptom, when the chemical evidence of proteid indigestion is absent, can with reasonable certainty be referred to amylaceous dyspepsia, with greater reason, indeed, than appears above, because the gastric hydrochloric acid retards bacterial activity, and an excess poured into the intestine markedly interferes with the digestion of starches. Confirmatory of this view is the observation of Kast, that neutralization of the gastric juice with sodium carbonate was followed by an increase of ethereal sulphates. Biernacki practically reaches the same conclusion, when he says that the excretion of putrefactive products is large, with great decrease of hydrochloric acid secreted. The further suggestion can be made that the gases due to proteid indigestion are sulphur-containing and consequently more obnoxious than those of the marsh-gas series of carbo-hydrate origin. Yet it must be borne in mind that gluten associated with the carbo-hydrates is a sulphur-containing body, so that this distinction is not so important as it would at first appear. Coincident with flatulence are the painful phenomena from heaviness, tenderness, and abdominal discomfort to colicky pains. Since flatulence is more marked with starchy than with proteid indigestion, these symptoms are more

prominent. Further, because constipation is an important factor; abdominal heaviness in addition to acute pain is frequently found. Not only are local physical signs, as fullness, tenderness and changes in percussion note more marked than in proteid indigestion, but the general symptoms are more numerous and persistent. The opportunity for absorption of peccant material—to use an old term—is favored by the constipation, but as has been stated, the ptomaines of decomposed starch (amulon-ptomaine) are almost as injurious to the human body as the ptomaines of nitrogenous foods. Therefore we note the lassitude, habitual malaise, general debility (partly from insufficient nutrition), the insomnia, the various sensory symptoms, headaches, vertical, frontal, or occipital, and vertigo. The heart symptoms are prominent, due in part to gaseous distention, and vary in importance from palpitation, cardiac distress, cardiac pain, and tachycardia to syncope. We have also the urticarias, the muddy complexions, cold hands and feet, referable to this cause. We may even observe marked mental changes as hypochondriasis, intellectual apathy and morbid somnolence.

The picture is a familiar one, but we all have doubtless failed many times in not differentiating this particular form of indigestion, and in attributing too much importance to the gastric, to the neglect of the intestinal digestion. After all, the diagnosis by exclusion, for such must be the method employed, and its accuracy can be readily put to the touchstone of clinical experience. Those, in whose persons starch is imperfectly digested, tolerate badly the starchy foods. The causes of the indigestion of starches are: (1) excessive ingestion of carbo-hydrates, (2) imperfect insalivation, (3) hasty mastication, (4) too diluted starch foods, (5) too great gastric acidity, (6) insufficient or perverted secretion of pancreatic fluid, (7) excess or abnormal activity of micro-organisms, (8) intestinal torpor or exaggerated peristalsis, and (9) imperfect absorption of already digested foods.

The diagnosis rests upon the positive evidence of constipation, flatulence, the sensory phenomena, the general systemic disturbances and remote painful symptoms existing in a marked degree, and upon the negative evidence as found in the ethereal sulphate-ratio and the amount of urinary indican. The picture seems clearly outlined, and at the close of our study we may say that the diagnosis of the indigestion of starchy food should be reached with reasonable certainty.

749 MADISON AVE.

CLINICAL MEMORANDUM.

ATAXIC SPEECH FOLLOWING THE USE OF TRIONAL.

BY J. C. WELCH, M.D.,
OF BELLEVUE, PENNA.

THE patient, aged 48 years, was a physician of good mental qualities, and of fine physique, who gave a history of having been addicted to the use of morphia for fourteen years. He administered it by mouth and hypodermically, ordinarily taking two grains hypodermically in the form of Magendie's solution. For a week previous to coming under the observation of the writer, he had been consuming a large quantity of whiskey. During this debauch he lost his hypodermic syringe, so that he was suffering from the absence of morphia, as well as from excess of liquor. He was restless and irritable, had insomnia and slight delirium; also had anorexia and diarrhea.

The patient was put to bed and ordered Trional, gr. xxx., every three hours, Tr. nux vomica, ℥xv., three times a day. Beef tea, milk, and light diet was administered at frequent intervals. The diarrhea was treated with bismuth and salol. During the following four days the patient slept $2\frac{3}{4}$, $7\frac{1}{2}$, 17, and 18 hours repectively. The trional was reduced to gr. xxx. morning and evening. During the next 24 hours he slept 7 hours, and during the next day, 14 hours. He was now noticed to be dull and bewildered, and complained of heaviness and numbness of the limbs, and of great mental depression. His speech was very ataxic; the difficulty of speech was apparently of central origin, and at first a beginning cerebral hemorrhage was feared. In the preceding six days, from two to two and one-half ounces trional had been taken. The administration of this drug was then entirely suspended, and caffeine and digitalis substituted. There was a gradual disappearance of all the unfavorable symptoms, the insomnia not returning. The patient remained in bed twelve days, in his room a week longer, and then went on a sea voyage under the care of a companion, and thus disappeared from further observation.

A MISTAKEN DIAGNOSIS OF HYSTERICAL AMBLYOPIA.

BY DR. HARRY FRIEDENWALD,
OF BALTIMORE, MD.

THE separation of cases of organic from those of functional disease of the nervous system is usually not difficult, especially when the patients can be kept under observation for some time. In some cases of organic nervous disease, however, the proper signs may be entirely wanting for diagnosis; they may be replaced by those that are more or less characteristic of hysterical affections. In other cases, again, the signs of true organic disease and those of functional disorders are so mingled that the diagnosis becomes a matter of the greatest doubt. Thus Dr. Buzzard (Brain, 1890) described a number of cases in which the diagnosis of hysteria had been made, and in time the true nature of the disease was shown to be disseminated sclerosis.

It is useful to call attention to these cases, for they

teach one to be very careful in diagnosis, and especially to go slowly before designating a case as "hysterical." The most careful examination will sometimes not save us from error. In the case which will be reported below, this error was of the most serious nature.

Before describing the case, it may not be out of place to mention that hysterical affections are sometimes met with in ophthalmic practice. The most common are functional disturbances of vision, without any ophthalmoscopic alterations. Central or peripheral vision may be affected. The fields of vision for the several colors and for white are usually altered. The case which is to be presented in this paper is one in which the diagnosis of "hysterical amblyopia" was made.

Mrs. A., aged 40, consulted me May 23, 1892, complaining that her vision had been dimmed for the past three months. The dimness was most noticeable during the day, and varied greatly. She had also had severe headaches. Her menopause had suddenly come on almost one year previously. Her family history was good. No ophthalmoscopic changes could be discovered. The papillæ were normal, excepting, perhaps, a slight pallor of the macular halves. V. R. E. 8/24; V. L. E. 4/60. The field of vision of the right eye was somewhat restricted in its outer and lower portions, but this was rather indefinite; there appeared to be indefinite central scotomata in both fields. A thorough physical examination did not reveal any symptoms of organic disease, the only exception being a very low specific gravity of the urine (varying between 1010 and 1003). The patient's general appearance and manners strongly suggested a hysterical condition.

The diagnosis of *retro-bulbar optic neuritis* was made. It was believed to have some connection with her menopause. She was treated with the red iodide of mercury, then with jaborandi, and later with mercurial inunctions and iodide of potassium. But her condition did not improve; for some time the vision of the right eye remained the same, while that of the left eye gradually diminished. August 21st, V. R. E. 8/24; V. L. E. could not count fingers, unless very close, and then with greatest difficulty. At this time there was a large defect in the outer lower portion of the left field of vision.

At this time a consultation was held with Dr. X., a well-known specialist in diseases of the nervous system. He was unable to find any signs of organic nervous disease.

The patient was then sent to Dr. Y., an eminent oculist of New York, for it was evident that the diagnosis of retro-bulbar neuritis was at least very doubtful. In that case we should have found definite ophthalmoscopic changes after such a length of time, and yet there were none. The diagnosis had, therefore, been changed to *hysterical amblyopia*.

Prof. Y.'s answer stated that he considered the affection "purely nervous." "There is an indication of sector-like temporal pallor, as in central scotoma." But he could find "no central scotomo, not even for colors. Her field is irregular; in the right, the outer lower quadrant is absent; in the left, the lower half; then again, she saw the hand in the lower half. V. R. E. at first 20/50, then with weakest glasses 20/30. Reads No. 2 Jaeger and should read No. 1, commensurate with V, for distance. The whole disease is a form of neurasthenia, and I am sure she will recover."

The great variations which had previously been noted by me, both in the fields of vision and in central vision, as well as those mentioned by Dr. Y., strengthened me in the belief that the diagnosis, concerning which we were all of one opinion, was correct. But treatment with this view, especially suggestive treatment, was without the slightest effect. Early in October, therefore, it was deemed wise to again have her undergo a thorough examination of her nervous system, and Dr. Z., a distinguished professor of Psychiatry was called upon. He likewise saw the patient a number of times, and concluded that the affection was of a purely functional character. Treatment with ergot, and later with tonics, did not improve her condition. She became somewhat dull, her memory began to fail, and the vision of both eyes gradually diminished. November 20, V. R. E. 8/60, V. L. E. could not count fingers. Still there was no ophthalmoscopic change.

During the latter part of December, as I was afterward informed, her gait became reeling, her limbs became weak, and her mental condition became much worse; she slept a great deal, her memory was very poor, and she spoke very little. At the same time her headaches had ceased. January 1, 1893, she lost control of the bladder, and became too weak to remain out of bed. Her condition gradually became worse, and on January 13th she died with symptoms of cerebral edema.

In the absence of a post-mortem examination, it is impossible to decide as to the cause of her complaints and of her death. But it was evident that the diagnosis of hysterical affection which was made by me, and with which several eminent physicians agreed, was a mistaken one.

There was certainly some organic cerebral affection which ran its course without involving any peripheral sensory or motor nerve, excepting the optic nerves, and produced no symptoms but diabetes insipidus, and toward the end, loss of mental power.

THERAPEUTIC NOTE.

Poisoning with Creosote.—At a recent meeting of the Société Médicale des Hopitaux Faisans (*Presse Médicale*, 1896, No 6) reported a case of chronic pulmonary tuberculosis that was being treated with injections of creosoted oil, 1.15—4½ ounces, representing more than two drams of creosote, being injected daily. The most conspicuous symptoms of the resulting intoxication were nervous in character and included especially delirium and dilatation of the pupils. The renal secretion was diminished and the urine was deeply colored, almost black. The prominence of the nervous phenomena raised a suspicion of tuberculous meningitis, but careful investigation disclosed the condition of toxic pseudomeningitis.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,

SATURDAY, FEBRUARY 15, 1896.

PRESIDENT PARK'S ADDRESS BEFORE THE NEW YORK STATE MEDICAL SOCIETY.

Those who attended the meeting in the Senate Chamber at Albany, Wednesday evening, January 29, 1896, were given an intellectual treat unusual in quality.

To a professional man who has made a well-deserved reputation in medicine or in surgery, there is no such thing as leisure. His days and his nights are consumed in the routine of his work, in doing what must be done, and in preparing for what is before him. If he be a teacher in medicine, the demands upon the hours he steals from the night and from his own repose are still greater. He cannot block out his time deliberately, as does the scholar or the literary man. If he gains an insight into the realms of science, or surveys fields of literature not in direct touch with the immediate work in hand, he must do so by systematic use of the momentary intervals that may occur between important engagements.

That by such a method it is ordinarily possible to gain a mastery of such a wide and intricate subject as Comparative Pathology, few of those favored ones who devote their entire time to investigation and thought would allow. But that such has been accomplished by the recent President of the New York State Medical Society, every one who heard him must admit.

There are no words but those of praise, not only for the selection of the subject which, of itself, was an inspiration to those possessed of the scholarly instinct and the spirit of investigation, but also for the masterly manner in which he surveyed the broad field of Comparative Pathology, as well as the familiarity with all forms of life that was displayed in his rapid review of the abnormalities presented by plants and animals. Throughout it all was noticeable a comprehension of the principles of evolutionary science that is rarely observed.

There were two propositions in President Park's address worthy of comment:

The first was, that it would be well if a society were organized for the study of Comparative Pathology, with a membership that would include all workers in each special department in which the abnormalities of every living thing are matters of observation and research. To the common fund of information each member would contribute, from the narrow field in which he worked exhaustively, his richest results and his most mature judgment; so that each, by comparing results attained in other analogous fields, and by determining points of similarity and of divergence, would broaden his own mental horizon and get a comprehensive insight into the general principles of pathological processes in all nature, impossible of attainment by any single worker in one department of life. That such an ideal is a credit to its originator, goes without saying.

The second proposition was, that, under the editorship of some man learned in all departments of nature—say Bland Sutton, for whom the President showed deserved respect—the accumulated observations of all investigators into nature's abnormal workings should be brought together in one work of several volumes; that these should be thoughtfully epitomized for the use of students, and that this condensed volume should be made

a text-book, the study of which should occupy some portion of the last two or three years in all our medical colleges.

The gathering together of the material for such a work is becoming yearly more easy of accomplishment, and that such a "system" will eventually be published seems more and more probable. But the study of pathology must be preceded by a thorough mastery of anatomy, both macroscopic and microscopic, of physiology, including physiological chemistry, and of embryology. Under prevailing conditions of admission to medical colleges, in order that Comparative Pathology may be taught at all, there must first be established competent courses in comparative anatomy and physiology. It is a question if, in a four years' course, there would be any time for the thorough mastery of comparative anatomy and physiology preparatory to the study of Comparative Pathology. The demands of every department in a medical curriculum are constantly increasing. There is now very great difficulty in giving students a fair comprehension of the essential facts which he must master in order to satisfy his college and the State before he can obtain his degree and his license to practice medicine.

If we could relegate to the preparatory course the subjects of botany, chemistry, physics, including electricity and refraction, morphology and histology, then perhaps it would be possible to introduce successfully in all our schools comparative methods in the teaching of anatomy, physiology, and pathology. For the great majority of colleges, however, such a day is far distant, and distant the more since the recent action of the State Society, sanctioning an amendment to the law permitting a student to enter a medical college conditioned on "one or more subjects" at present required by the State before he can receive a "medical student's certificate" which he is now compelled to earn before he can matriculate in any medical college in the State.

In the present state of medical education, he who would gain a competent knowledge of Comparative Pathology must imitate our President and abstract the time necessary for it from the hours of his own rest and recreation, or seek special schools

THE ANTIVIVISECTION BILL IN CONGRESS.

In another column we print a detailed account, by our special correspondent, of the hearing before the District Commissioners on Senate bill 1552, to which we invite the careful consideration of the medical and scientific professions. The bill is printed in full, together with a list of the Senate and House Committees through whose hands this bill will pass, before it reaches the floor for general consideration. These details are given with a purpose. First of all, the medical men of the country should know the exact contents of the bill, and the edition printed by Congress is so limited that it is impossible for our Washington confrères to obtain a sufficient number of copies for distribution. In the next place, it is important for the medical profession to know exactly who the Senators and Congressmen are to whom this bill has been referred for careful consideration. These senators and congressmen should be informed by the medical and scientific men of their respective States of the absolute absurdity of this bill and of its injustice to science, and we urge that members of the profession in the States from which these Senators and Representatives come, take immediate action, and bring the proper information to the attention of each and every member of the two committees.

The suggestion made by our special correspondent that this movement in Washington may be the beginning of a national movement is worthy of attention. The bill, though primarily intended for the District of Columbia, is not one of merely local interest, and if not killed in committee will give the antivivisectors in various parts of the country an unduly exaggerated idea of the justice(!) of their movement. This *local* bill is one of *national* interest to the medical profession. If it is reported to the Senate and the House we may expect to see similar and even more radical bills presented to many of the State legislatures within a short time. Let us all unite, therefore, in making a national fight at Washington, and in giving this bill such a severe and total defeat that it will never again be allowed to see daylight.

We desire to call particular attention to several points in the bill. First of all, the bill is misnamed. The title should read: "A bill for the

prevention of advance in medical science in the District of Columbia, and for the prevention of the application of discoveries already made." This exactly expresses the result the bill would attain if allowed to become a law. The question naturally arises whether the bill could be amended so as to suit all parties. To this we reply in the most emphatic language, No! The bill is too radically wrong to permit of satisfactory amendment.

The very *general* character of the bill should attract attention: "That hereafter no persons shall perform on *any living animal any experiment* calculated to give pain to such animal, except subject to the restrictions hereinafter prescribed." *Any living animal!* That statement is sweeping; and our friends who proposed the bill could not have realized all it implies.

Section 2 deserves especially close attention, for it absolutely prohibits all experimentation in bacteriology; it practically compels the use of ether or chloroform in every hypodermic given to animals, and in the preparation of vaccine; by the provisions of this section experiments to test dogs for hydrophobia are also excluded.

But of all the faulty provisions, section 6 is the extreme *par excellence*. The Commissioners of the District are to appoint an agent of the Humane Society to inspect the laboratories; "special inspectors—who may be willing to act as such inspectors gratuitously," are also provided for. It is but natural that the most hysterical fanatics will make application for such appointment, and we would thus see the surgeon-generals of the Army, Navy and Marine Hospital Service, as well as the chief of the Bureau of Animal Industry made subject to supervision by a local society composed of persons who are absolutely ignorant of the conditions governing the experiments upon which they would report.

Section 5, providing for reports of experiments to be made to the Commissioners, is equally harmful, and would lead to premature publication through the daily newspapers of half-finished results.

The press reports of the hearing before the Commissioners show that the vivisectionists condemned brutality as well as did the antivivisectionists, and all thinking men will agree with them in this. It has not yet been shown, however, that such brutality exists in this country, as the antivivisectionists would have us believe.

Washington is the best place in the country to fight this question out to the finish, for this bill, and *any similar bill* would seriously handicap the workings of the four sanitary departments of the national government, *i.e.*, the Marine Hospital Service, the Bureau of Animal Industry, and the medical services of the Army and Navy, and any legislation which affects their work, more especially the work of the Bureau of Animal Industry, will also affect the State Boards of Health throughout the country; for at the present moment the bureau is furnishing tuberculin and mallein to many of these boards. The present bill would result in stopping this supply of material now used in many States. The attention of the State Boards is called to this point, and we urge them to immediately enter urgent protests against any legislation of this or of similar character.

Washington is perhaps the centre of animal experimentation in this country at the present moment, and we can rely upon our scientists there to oppose this measure to the full extent of their influence, but as we would all be affected more or less directly by national legislation, it behooves the medical profession and the scientific world generally to move in this matter with promptness.

The legal question of making governmental departments subject to revision and inspection by the District Commissioners, or by volunteer inspectors of a local society of laity, is a point for careful consideration.

GENITO-URINARY AND VENEREAL DISEASES AND SYPHILOLOGY.

A CRITICAL RÉSUMÉ OF RECENT ADVANCE: LINEAR ELECTROLYSIS IN STRICTURE OF THE URETHRA.

AMERICAN surgeons many years ago reached the conclusion that electrolysis for the treatment of stricture of the urethra when metallic, olivary tips seated at the end of the flexible bougie were employed, was not curative, and that it might produce a still greater stenosis of the canal. If the electrolytic action, or, we may say, affinity, could be brought to bear on the stricture tissue, and if we could then produce its absorption, the

method of treatment would certainly be an ideal one. Unfortunately this result could not be produced, for when the current was sufficiently strong, the electro-chemical action was expended upon the mucous membrane, the disintegration or destruction of which would occur before the fibroid stenosis could be acted upon. It is thus rendered plain why the treatment was a failure, and its use very often a danger, since by it the mucous membrane, so essential to the formation of a restored urethra, was destroyed, and a ragged, cicatricial canal was left, which promptly became more stenosed than it was before the operation. This having been our experience, and such being our conclusions, it can be readily understood that several genito-urinary surgeons of this city were both skeptical, and even impatient, when a new method of treatment of urethral stricture by electrolysis was brought to their notice by its inventor, Dr. Fort, the professor of anatomy of the Faculty of Medicine of Paris. In a recent essay ("Electrolyser for the Surgical Treatment of Stricture," *New York Medical Journal*, November 16, 1895, and *Traitement des Rétrécessements par l'Électrolyse Linéaire*, Paris, 1894), Dr. Fort describes his instrument, the *technique* of the operation, its immediate symptoms, and its remote results. The author of this review placed at Dr. Fort's disposal fifteen hospital cases of stricture, and has carefully studied the operative methods and the condition of the patients after operation. The electrolyser resembles in a general way Maisonneuve's urethotome when the filiform guide has been attached and the knife has been pushed down the grooved staff. It really consists of two nearly equal parts, the distal one being the filliform guide and the proximal one being a fine, soft bougie (calibre about 6 or 8 French scale), through the whole length of which there is a thin, metallic wire. This wire, just before the junction of the proximal with the flexible distal portion, is bent so as to form an obtuse conical projection, which resembles the blade of Maisonneuve's instrument. This platinum blade, therefore, is the active agent in the operation. The filiform guide is passed down the urethra until the electrolytic blade (as we may call it) rests on the face of the stricture. The instrument is then connected with the negative pole of a continuous current battery and the positive pole, which is flat and of the size of one's palm, is placed near the penis, either on a thigh or on the lower part of the abdomen. The current is then turned on. This should be, in general, of a strength of ten milliamperes, as shown by an attached galvanometer. During the operation, the electrolytic blade remains cool, and is gently pushed downward by the surgeon, and in many cases traverses the strictured tissue in less than a minute; but in very firm, dense, and quite long strictures, two or three minutes may elapse before the operation is complete. In cases in which there are several strictures seated at a distance from each other, more time is consumed. Haste, however, is not at all essential in these cases; indeed, it seems to the writer that a more lasting effect is produced if the blade is allowed to traverse the tissues very slowly. In this way, in all probability, a more potential action is produced. In the judgment of the writer, better results will follow in very dense and extensive strictures if the action of the current is prolonged. In all cases, copious irrigations with mild antiseptic solutions should be used, both before and after the operation. In this connection, it may be remarked that before operation Dr. Fort threw into the bladder, in most cases using considerable force, several, even many ounces of an antiseptic solution, without any untoward result. He did the same after the operation, seeming to care nothing about the force which he exercised upon the compressor urethrae muscle. On the withdrawal of the blade, the evidence of the electrolytic action is seen in the little mass of disintegrated, perhaps slightly effervescent, tissue which comes away with it. In general, it may be stated that the operation is nearly painless; some patients make an outcry from fear, while others complain of a slight stabbing sensation. There may be no hemorrhage at all, or the flow of blood may be slight; it never is sufficient to cause any uneasiness. With our precise antiseptic methods, Maisonneuve's operation may now be done in most cases without fear of sepsis, and, as a rule, little or no fever is present. It is remarkable to observe how free patients operated upon by Fort's method are from febrile movement or any troublesome symptom. The writer was struck by the

calm confidence of the Paris professor in not sending patients operated upon to bed; indeed, in some cases, he allowed them to go out of the hospital, enjoining them to return for subsequent irrigation and dilatation. This course seemed startling to cautious surgeons who, in the past, even when using intelligent antisepsis, were always a little anxious for a patient after a Maisonneuve's operation; still, in more than a dozen cases, the writer has seen no untoward result.

Another point which is to be commended is developed in the after-treatment of strictures thus operated upon by Dr. Fort. He contents himself in these cases with the passage of olivary bougies of a maximum calibre of 24 French scale. In this conservative course he has the warm endorsement of the writer, for it is his firm conviction that if the lumen of a man's urethra, after an operation for organic stricture, can be maintained at a calibre of 24 French scale, that man is a lucky individual, and will be in far better condition (and certainly will not be in jeopardy) than if he were persistently treated with much larger sounds. Judicious treatment of strictured urethrae after operations is just as important as the cutting operation itself. From a study of the fifteen cases already mentioned, the writer is led to think that Dr. Fort's method is applicable to annular and bridle strictures in which the stricture tissue is not exceedingly dense or too exuberant. It is not a treatment, as a rule, by which a route can be tunneled through long, very dense, and copious inodular urethral stenoses. Thus, in the case of a man having a well-defined, not very long or thick stricture, at four inches down the canal, this contraction readily yielded to the electrolyser, while a large, dense, inodular stricture mass at the bulbo-membranous junction was wholly unaffected, and only traversed by Maisonneuve's guide and knife. Again, in another case, there was a stenosis of the urethra beginning just behind the glans and extending into the subpubic course, and having a length of four inches and a calibre of 8 French scale, the electrolyser could make no headway whatever. In this case, gradual dilatation is producing good results. The writer feels confident that many cases of firm stricture in the bulbous urethra may be traversed by Fort's instrument, whereas most New York surgeons would have in the past subjected them to external urethrotomy. The electrolyser may lessen the number of cases of external urethrotomy, but it will not render the operation obsolete. The electrolyser is useful, in that it decomposes a segment of the stenosed urethral canal, and then by destruction of tissue, gives more relief than the thin incision of Maisonneuve's blade, and it does this with precision and almost without hemorrhage. Added to this, there need be no septic complications. Of the ultimate outcome of the operation, the writer cannot speak with authority, but it is fair to assume that if gradual dilatation is regularly, carefully, and persistently followed for a long period, the man may be wholly free from all distressing or dangerous symptoms, and he may void his urine with complacency and comfort.

Robert W. Taylor, M.D.

ECHOES AND NEWS.

Recent telegraphic advices from Santiago de Cuba state that hemorrhagic smallpox is now raging among the soldiers stationed there.

A communication from Denver, Col., February 6, 1896, states that it is currently reported that Schlatter, the alleged new Messiah, has perished in a storm in New Mexico.

An appeal has been made to the general public for subscriptions which will enable the admirers of the late Prof. T. H. Huxley to erect his statue beside those of Darwin and Owen in the Natural History Museum, South Kensington, England. It is gratifying to notice that this very proper tribute of respect to the great English scientist is meeting with substantial encouragement.

Dr. H. Ernest Goodman of Philadelphia died suddenly last week. Dr. Goodman was a prominent physician and connected with the Medico-Chirurgical College and Hospital of that city.

The first meeting of the Utah State Medical Society has given evidence of the good quality of the members of the profession in this the latest member of the sisterhood of States. It was declared the sense of the society "that every member of it interest himself personally in securing the election of men for the next Legislature who favor the maintenance of a high standard of medical excellence in the State of Utah".

In his race for United States Senatorship Dr. Hunter, of Kentucky, displays the true professional tenacity embodied in the homely phrase, "While there is life there is hope."

Dr A. B. Hirsh has been elected president of the Medico-Legal Society of Philadelphia.

Dr. Unna again offers a prize for original work. The subject for 1896 is: "The Behavior of the Epithelial Fibrils During the development of Soft Nævi and Alveolar Carcinoma." The amount offered is 900 marks. For further particulars, the reader is referred to L. Voss, 34 Hohe Bleichen, Hamburg.

"Public Health" is the name of a new quarterly journal of sanitation to be published at Philadelphia by Dr. W. B. Atkinson as the organ of the associated health authorities of Pennsylvania, the State Board of Health and the State Quarantine Board.

At the International Congress of Obstetricians and and Gynecologists to be held at Geneva, Switzerland, in September of this year, one of the questions for discussion will be the "Relative Frequency and most Common Forms of Contracted Pelvis in Different Countries, Groups of Countries and Regions." To Dr. Wm. T. Lusk of New York city, is assigned the duty of collecting information from the United States. He has issued blank forms for reports which can be had on application by any one having observations and statistics to offer.

It is rumored that a new monthly journal to be known as the *Medical Council*, will shortly appear in Philadelphia. Its pages are to be especially devoted to obstetrics, diseases of women and children, including racial improvement.

The Jefferson Medical College of Philadelphia has shown great enterprise in securing Prof. Turck, of Chicago, who began, February 3d, a course of ten lectures, under the auspices of that institution, upon the laboratory investigation of bacteriology, pathology, and upon general scientific research, with especial reference to diseases of the alimentary tract. One of the most gratifying results of these lectures is the stimulus that has been given to individual desire for original investigation, and a general awakening to the importance of well equipped laboratories for such work.

The number of students attending the medical department of some of the German universities for the Winter, semester of 1895-1896, is as follows:

	Natives.	Foreigners.	Total.
Berlin . .	883	375	1258
Munich . .	516	677	1193
Wurzburg . .	182	532	714
Leipsic . .	347	320	667
Erlangen . .	187	187	374
Greifswald .	316	35	351
Freiburg . .	85	240	325
Breslau . .	310	6	316
Strassburg .	160	152	312

It is stated that on the 10th inst., at the experimental laboratory of the Central Röntgen Association in Berlin, there was presented for examination, a young seamstress who had swallowed a needle the week previous. She had constant hematemesis and other symptoms of ulceration. The X-ray revealed the needle lying point downward in the right lower part of the stomach. Considerable ulceration being present, it was resolved to operate at once. The patient was placed under chloroform and the needle found as indicated and removed. The patient is progressing favorably.

It is reported by cable from Berlin that Professor Brieger has finally succeeded in freeing the diphtheria toxin from all albuminous compounds. In an article in the July number of the *Zeit. f. Hygie. Infect.*, Professor Brieger stated that as he obtained the toxin more and more nearly in a pure state, the chemical reactions became less and less, and he there stated that he believed these reactions were due to the albuminous compounds thrown down with the toxin and not to the toxin itself. If he has actually obtained toxin in a pure state, he has accomplished an important advance, which may lead to the discovery of methods of separating the toxin, and possibly to manufacture it chemically.

At the annual meeting of the Kings County Medical Association, the following officers were elected: President, J. C. Burwirth; vice-president, L. A. W. Alleman; recording secretary, F. C. Raynor; corresponding secretary, J. Scott Wood; treasurer, E. H. Squibb; member executive committee, Jonathan Wright.

Dr. Geo. M. Gould, 925 Walnut street, Philadelphia, requests librarians of medical societies, colleges, and associations to send him lists (with precise dates, etc.) of such periodicals as they need to complete their files.

He also begs physicians (or legatees) to send him accurate lists of such periodicals (or books) as they are willing to donate to libraries. Lists only are desired, not the periodicals themselves, until, after correspondence, it shall have been determined: 1. Where they are needed; 2. Where they will be properly cared for; 3. Where they will do the most good to medicine.

It is Dr. Gould's intention to aid established libraries in completing their files by thus forming a kind of (gratis) Exchange, and to encourage the formation of new public medical libraries by utilizing some of the vast number of valuable medical publications at present going to waste or destruction.

NEW INVENTION.

A CONVENIENT INSTRUMENT FOR VISUAL USE IN DIAGNOSIS WITH THE ROENTGEN RAYS.

By W. F. MAGIE Ph.D.,
PROFESSOR OF PHYSICS IN PRINCETON COLLEGE,
PRINCETON, N. J.

The instrument here proposed for examination with the Röntgen rays I have not seen described elsewhere, and therefore present a brief account of it in the hope that it will be of use to investigators in this interesting subject.

A sheet of black paper, coated on one face with platinum-bari cyanide, is placed with the coated side inward across the end of a tube or box, into which the observer looks, and which is so fitted to the face or shielded by cloths that

the phosphorescent substance and the eyes are protected from all extraneous light. If this tube be then directed toward the excited Crookes' tube, which is giving the Röntgen rays, the phosphorescent paper in the tube glows, and the shadows of objects interposed between it and the Crookes' tube appear upon it. The advantage of this arrangement consists in its avoiding the experimental inconvenience of working in a dark room, and likewise the delays involved in the plan used by Röntgen. By this instrument the phenomena of the Röntgen rays can be most conveniently investigated. Its obvious applicability in diagnosis has led to my giving an account of it here. A more detailed account, with a report of cases in which it has been used, will appear in the March number of the *American Journal of the Medical Sciences.*

PRINCETON COLLEGE, Princeton, N. J., Feb. 7, 1896.

CORRESPONDENCE.

MONTREAL, Can., February 10.

[BY TELEGRAPH TO THE MEDICAL NEWS.]

I BEG to state that at the fortnightly meeting of the Medico-Chirurgical Society of Montreal, held on Friday night, February 7th, Prof. Cox of the science department of the McGill University, gave a demonstration of Professor Rontgen's cathode photographic methods, and exhibited photographs of a bullet in a man's leg. The patient had been shot in the leg some months ago, and in spite of every effort the surgeons were unable to locate the bullet. As the man was suffering a great deal, Prof. Cox undertook to discover it by cathode photography, and after developing the plate, the bullet was faintly seen between the tibia and fibula, from whence it will be an easy matter to remove it. Great interest was shown in the experiment, and nearly every member of our society was present as well as surgeons from Toronto and other cities who had been invited. The great value to surgery of this advance in science was fully recognized.

A. LAPTHORN SMITH, M.D.

ANTIVIVISECTION BILL IN CONGRESS—HEARING BEFORE THE COMMISSIONERS OF THE DISTRICT OF COLUMBIA.

[SPECIAL CORRESPONDENCE TO THE MEDICAL NEWS.]

THE antivivisection scarecrow has suddenly come to life again at Washington, D. C., and the Humane Society of the District of Columbia has succeeded in having a bill introduced into both houses of Congress which calls for immediate attention from the scientific and medical professions in every quarter of this country. As it is very difficult to procure copies of this bill for distribution, owing to the limited edition printed under the present law, the entire text of the bill in question is given here for the benefit of those whose active interest it should command.

Fifty-fourth Congress, First Session: { *S. 1552.* / *H. R. 4446.*

IN THE SENATE OF THE UNITED STATES.

JANUARY 14, 1896.

Mr. McMillan introduced the following bill, which was read twice and referred to the Committee on the District of Columbia

A BILL

FOR THE FURTHER PREVENTION OF CRUELTY TO ANIMALS IN THE DISTRICT OF COLUMBIA.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That hereafter no person shall perform on a living animal any experiment calculated to give pain to such animal, except subject to the restrictions hereinafter prescribed. Any person performing, or taking part in performing, any experiment calculated to give pain, in contravention of this Act, shall be guilty of an offense against this Act, and shall, if it be the first offense, be liable to a penalty not exceeding one hundred and fifty dollars, and if it be the second or any subsequent offense, shall be liable, at the discretion of the court by which he is tried, to a penalty not exceeding three hundred dollars, or to imprisonment for a period not exceeding six months.

SEC. 2. That the following restrictions are imposed by this Act with respect to the performance on any living animal of an experiment calculated to give pain to such animal; that is to say:

(*a*) The experiment must be performed with a view to the advancement by new discovery of physiological knowledge, or of knowledge which will be useful for saving or prolonging life or alleviating suffering; and

(*b*) The experiment must be performed by a person holding such license from the Commissioners of the District of Columbia as is in this Act mentioned; and

(*c*) The animal must, during the whole of the experiment, be completely under the influence of ether or chloroform to prevent the animal feeling pain; and

(*d*) The animal must, if the pain is likely to continue after the effect of the anesthetic has ceased, or if any serious injury has been inflicted on the animal, be killed before it recovers from the influence of the anesthetic which has been administered; and

(*e*) No experiment shall be made upon any living creature, calculated to give pain to such creature, in any of the public schools of the District of Columbia; provided as follows, that is to say:

First. Experiments may be performed under the foregoing provisions as to the use of anesthetics by a person giving illustrations of lectures in medical schools, hospitals, or colleges, or elsewhere, on such certificate being given as in this act hereafter mentioned, that the proposed experiments are absolutely necessary for the due instruction of the persons to whom such lectures are given, with a view to their acquiring physiological knowledge or knowledge which will be useful to them for saving or prolonging life or alleviating suffering;

Second. The substance known as urari or curare shall not, for the purposes of this Act, be deemed to be an anesthetic; and

Third. Notwithstanding anything in this Act contained, no experiment calculated to give pain shall be performed on a dog or cat, except upon such certificate being given as in this Act mentioned, stating, in addition to the statements hereinbefore required to be made in such certificate, that for reasons specified in the certificate the object of the experiment will be necessarily frustrated unless it is performed on an animal similar in constitution and habits to a cat or dog, and no other animal is available for such experiment; and an experiment calculated to give pain shall not be performed on any horse, ass, or mule, except on such certificate being given as in this Act mentioned, that the object of the experiment will be necessarily frustrated unless it is performed on a horse, ass, or mule, and that no other animal is available for such purpose; and

Fourth. Any exhibition to the general public, whether admission be on payment of money or gratuitous, of experiments on living animals, calculated to give pain, shall be illegal.

Any person performing or aiding in performing such experiment shall be deemed to be guilty of an offense against this Act, and shall, if it be the first offense, be liable to a penalty not exceeding one hundred and fifty dollars, and if it be the second or any subsequent offense, shall be liable, at the discretion of the court by which he is tried, to a penalty not exceeding three hundred dollars or to imprisonment not exceeding six months; and any person publishing any notice of any such intended exhibition by advertisement in a newspaper, placard, or otherwise, shall be liable to a penalty not exceeding ten dollars.

A person punished for an offense under this section shall not for the same offense be punishable under any other section of this Act.

Sec. 3. That the Commissioners of the District may insert, as a condition of granting any license, a provision in such license that the place in which any such experiment is to be performed by the licensee is to be registered in such manner as the said Commissioners may from time to time by any general or special order direct: *Provided*, That every place for the performance of experiments for the purpose of instruction shall be approved by the said Commissioners, and shall be registered in such manner as the said Commissioners may from time to time by any general or special order direct.

Sec. 4. That the Commissioners of the District, upon application as hereinafter prescribed, may license any person whom they may think qualified to hold a license to perform experiments under this Act. A license granted by them may be for such time as they may think fit, and may be revoked by them on their being satisfied that such license ought to be revoked. There may be annexed to such license any condition which the said Commissioners may think expedient for the purpose of better carrying into effect the objects of this Act, but not inconsistent with the provisions thereof.

Sec. 5. That the Commissioners of the District may direct any person performing experiments under this Act from time to time to make reports to them of the result of such experiments, in such form and with such details as the said Commissioners may require.

Sec. 6. That the Commissioners of the District shall cause all registered places to be from time to time visited by inspectors without previous notice, for the purpose of securing compliance with the provisions of this Act, and shall appoint and authorize an agent of the Washington Humane Society to make such inspection, and may also appoint such special inspectors as they may think fit, either permanently or temporarily, who may be willing to act as such inspectors gratuitously.

Sec. 7. That any application for a license under this Act, and for a certificate to be given as in this act mentioned, must be signed by three physicians duly licensed to practice and actually engaged in practicing medicine in the District of Columbia, and also by a professor of physiology, medicine, anatomy, medical jurisprudence, materia medica, or surgery in the medical department of any duly established and reliable school or college in the District of Columbia: *Provided*, That when any person applying for a certificate under this Act is himself one of the persons authorized to sign such a certificate, the signature of some other of such persons shall be substituted for the signature of the applicant.

A certificate under this section may be given for such time or for such series of experiments as the persons signing the certificate may think expedient.

A copy of any certificate under this section shall be forwarded by the applicant to the Commissioners of the District but shall not be available until one week after a copy has been so forwarded.

The Commissioners of the District may at any time disallow or suspend any certificate given under this section.

Sec. 8. That the powers conferred by this Act of granting a license or giving a certificate for the performance of an experiment on living animals may be exercised by an order in writing, under the hand of any judge of a court of record having criminal jurisdiction in the District, in a case where such judge is satisfied that it is essential for the purposes of justice in a criminal case to make such experiment.

This bill has been referred to the Senate and House Committees on the District of Columbia, composed of the following members:

SENATE COMMITTEE.

Hon. Jas. McMillan, Mich.	Hon. J. B. Wetmore, R. I.
" J. H. Gallinger, N. H.	" I. J. Harris, Tenn.
" H. C. Hansbrough, N. D.	" C. J. Faulkner, W. Va.
" Redfield Proctor, Vt.	" C. H. Gibson, Md.
" J. C. Pritchard, N. C.	" Jas. Smith, Jr., N. J.
" Lucien Baker, Kas.	" T. C. Martin, Va.

Hon. A. O. Bacon, Ga.

HOUSE COMMITTEE.

Hon. Joseph W. Babcock, Wis.	Hon. Alfred Milnes, Mich.
" Alfred C. Harner, Penn.	" G. L. Wellington, Md.
" Geo. M. Curtis, Iowa.	" J. D. Richardson, Tenn.
" Geo. W. Hulick, Ohio.	" H. W. Rusk, Md.
" R. C. Schannon, N. Y.	" James E. Cobb, Ala.
" J. H. Huling, W. Va.	" E. E. Meredith, Va.
" B. B. Odell, Jr., N. Y.	" Jo Abbot, Texas.

Hon. Seth W. Cobb, Mo.

In accordance with custom, both committees have referred the bill to the Commissioners of the District of Columbia for consideration, and at present it is in their hands.

The antivivisectionists, it is understood, applied for a private hearing before the commissioners, but the medical scientists of the district objected. Dr. Busey, as president of the District Medical Society, protested against any private hearings on the subject, and the Commissioners were thus led to appoint Thursday, January 30th, as the time for a general hearing.

The Humane Society was represented by its Antivivisection Committee, as follows: Mrs. C. Kennedy, Mrs. H. B. F. MacFarland, Mrs. H. V. Boynton, Mrs. W. Knowlton, Miss Peet, Gen. Rufus Saxton and Mr. MacFarland.[1] There were also present among the antivivisectors: Rev. Dr. Power, Mrs. E. Totten, Gen. H. V. Boynton, Mr. W. Knowlton, and ex-Commissioner Douglass; and Dr. Leffingwell, of Cambridge, Mass.

The medical profession was represented by Drs. Busey, Magruder, and Kleinschmidt of the Committee on Legislation, District Medical Society; Surgeon General Sternberg and Dr. Walter Reed, of the U. S. Army; Dr. J. J. Kinyoun, of the U. S. Marine Hospital Service; Dr. D. E. Salmon, chief of the U. S. Bureau of Animal Industry, with his assistant chief, Dr. Brumbaugh, his biochemist, Dr. de Schneinitz, his pathologist, Dr. Moore, his medical zoölogist, Dr. Stiles, and Dr. Schroeder, director of the experiment station; Health Officer Woodward, Dr. G. Wythe Cook, Dr. Sowers and others.

Mr. Kennedy opened the discussion by reading the bill, after which he stated that there is no law at present in the United States regulating or prohibiting vivisection except in Massachusetts, where a law exists controlling experiments upon animals in the public schools. He then read extracts from the Report of the English Commission on Vivisection of 1876, and spoke of the brutalities practiced by scientists.

Mr. Ross Perry, one of the ablest lawyers of Washington, then followed with a lengthy address, which was evidently intended to be in support of the bill. Some of Mr. Perry's remarks are worthy of a moment's attention, coming from such a well-known man, and being so radical and hysterical in their character. They were received by the agitators with delight, and will undoubtedly be used by them hereafter in their pamphlets.

He claimed in the most radical manner that the end attained did not justify the means used; that knowledge purchased at the price of sufferings of animals was purchased too high.

Dr. Busey was the first to speak against the bill. He remarked in a quiet, sarcastic manner, that he appeared before the Commissioners expecting to hear a discussion on the subject of vivisection, but as a matter of fact he had only heard long addresses in which the medical profession had been attacked as inhumane and brutal, and as liable to finally end by vivisecting idiots and criminals. He then directed attention to sections 2 and 6 of the bill which he claimed made the bill *prohibitory*, instead of regulating the practice.

At this junction the antivivisectionists showed that they intended to interrupt him as frequently as possibly and thus try to gain time and points. Mr. Kennedy was the first to institute these tactics, but Dr. Busey soon succeeded in bringing him to silence.

Dr. Busey brought forward an array of facts in favor of vivisection which was evidently a surprise to the opposite party, and which came directly home to the women present by referring to the practical application of transfusion of blood in its relation to flooding after delivery, etc.

Surgeon-General Sternberg was the next speaker for the scientists, but, by request, he ceded the floor to Dr. Leffingwell, of Cambridge, Mass, whose time in Washington was limited. The antivivisectionists evidently were disappointed by the remarks of the Doctor, for he practically killed the bill for them, so far as the Commissioners are concerned. He admitted Dr. Busey's statements regarding the value of vivisection in science, and stated that if it were a question between vivisection and antivivisection, he would stand by vivisection. He desired to see vivisection restricted, but admitted that the bill under discussion was not satisfactory to this end.

Commissioner Truesdell then suggested that Dr. Leffingwell submit in writing for consideration of the Commissioners any suggestions he had to make, and the floor was given to General Sternberg.

As soon as General Sternberg began to speak, the antivivisectionists resumed their tactics of interruption, one after another propounding questions or making statements calculated to lead the speaker away from his train of thought.

The discussion here became stormy in the extreme, and the constant interruptions so exasperating that Dr. Salmon protested against their continuance. After this, Dr. Sternberg was able to finish his remarks in comparative quiet.

About three hours had been occupied by the hearing, and when time for adjournment had arrived, only two of the opponents had had an opportunity to speak. The bill is still in the hands of the Commissioners, who will refer it back to the Congressional Committees for report to Congress.

Several important matters come up in connection with this bill in Congress: *First.*—Is not this the beginning of a concerted action on the part of the antivivisectionists in various parts of the country? The importation of Dr. Leffingwell from Cambridge gives some plausibility to this view. *Second.*—If such is really the case, is it not time for the scientific and medical men of the country to be on their guard in the various States, to see that no State legislature passes any bill which will seriously compromise scientific research? But if there is no organized movement of this nature, this bill, even if reported to the two houses, may be followed by serious results, for fanatics will be encouraged by the apparent "importance" of their movement, and we may look for the introduction of extreme measures in many of the State legislatures.

[1] Names are taken from the *Washington Times*, January 31st.

OBITUARY.

Dr. James Edmund Reeves died at Chattanooga, Tenn., on January 4th, in his 67th year. He had been ill for a relatively short time with some obscure affection of the liver. Dr. Reeves was born in Annisville, Va., and after an apprenticeship in the office of his preceptors, he began at the age of 21 the practice of medicine in Sutton, W. Va. A year later he took a course of lectures at Hampden Sydney Medical College, of Richmond. Nearly ten years later he took a second course of lectures in the Medical Department of the University of Pennsylvania.

While a resident of Wheeling, W. Va., he agitated the subject of municipal hygiene and secured the passage of an ordinance establishing a city health department. In 1869 he was elected city health officer and county physician, and continued in office for four years. Subsequently he served as a member of City Council for four years. He was the author of a law creating the State Board of Health of West Virginia, of which he was a member, and for five years the secretary. For about the last six years he lived at Chattanooga.

Dr. Reeves was one of the founders of the American Public Health Association, and its president in 1885. In 1867 he issued a call for the organization of the State Medical Society of West Virginia, whose first secretary he was, and in 1881 its president. He was a member of the Executive Committee for West Virginia, of the International Medical Congress, held at Philadelphia in 1876. In 1882 he was elected a member of the Judicial Council, and in 1895 a trustee of the American Medical Association, and a member of the Association of American Physicians. He was one of the vice-presidents of the section of Public and International Hygiene of the International Medical Congress, held at Washington in 1887; vice-president of the American Microscopical Society in 1886; a member of the Advisory Council of the Pan-American Medical Congress, held at Washington in 1893. He was employed by the State Board of Health of Tennessee to make sanitary inspections of the State's defences against yellow fever during the Jacksonville epidemic of 1888.

In addition to numerous journal articles Dr. Reeves was the author of "A Practical Treatise on Enteric Fever," and a "Manual of Medical Microscopy for Students, Physicians and Surgeons."

The last signal service rendered the medical profession by Dr. Reeves was his brave and successful fight against quackery in the special form of a "consumption-cure." As is well known to the readers of the News, Dr. Reeves was sued for libel, but the jury, before which the case was tried, brought in a verdict in his favor ten minutes after the evidence had all been in, the closing speeches made, and the judge's instructions given. To the credit of the profession, the expenses of this suit, on the part of Dr. Reeves, were made good by voluntary contributions by a considerable number of physicians.

Dr. Reeves was the type of man that the profession can ill afford to lose—broad-minded, progressive and aggressive, rigidly honest and ethical. The profession of medicine is nobler that he has lived.

REVIEWS.

Catarrhal Diseases of the Respiratory Passages. Carter. Pp. 135. Chicago: E. H. Colegrove & Co., 1895.

It is difficult to properly characterize the series of fourteen papers contained in the book, or to determine the purpose of their publication. At any rate, undue prominence has been accorded lake winds and ozone in the etiology of tonsillitis. The author thinks that in cases of "catarrhal sore throat" the inhalation of menthol produces better results in damp than in dry weather. The chapter on the distribution of croup, bronchitis, etc., contains many interesting facts, and is responsible for the presence of Burmah, Dutch Guiana, and Zululand in the very complete index. Venezuela has for some cause been omitted. The extensive bibliography at the end of the book is doubtless valuable, but has its defects. Parkes' *Hygiene* and the Medical News are both mentioned, but are not visibly connected with any statement made by the author.

Die Lehre von den Naseneiterungen. Grunwald. Zweite ganzlich umgearbeitete Auflage. S. IX. u. 283. München: J. F. Lehmann, 1896.

When Grunwald published in 1892 the first edition of his monograph upon the pus-producing affections of the nose and accessory sinuses, it was generally conceded to be the most important contribution to rhinology of the year. There was so much that was valuable and stimulating, and so many subjects looked at in a new light, that some of us wondered whether all that the author said could be true. Grunwald's originality of treatment is perhaps best displayed in his discussion of "Ozena." His clear-cut convictions are not very moderately expressed, notwithstanding the fact that they contradict generally accepted theories. A second notable section of the work is that devoted to empyema of the sphenoidal sinuses, of which thirty-seven chronic cases are reported by the author. Although there is a markedly polemical complexion to many portions of the book, it is in an even greater measure rich in instructive clinical data, and while we cannot subscribe to everything contained in the work, we shall, at any rate, be constrained to perfect ourselves in the diagnosis and treatment of the somewhat obscure and elusive affections therein discussed.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 14, 1896, to February 3, 1896.

1st Lieutenant James M. Kennedy, Assistant Surgeon, is relieved from duty at Camp Merritt, Montana, to take effect upon the expiration of his present leave of absence, and ordered to Fort Missoula, Mon., for duty.

The leave of absence granted Captain James D. Glennan, Assistant Surgeon, is extended one month.

Leave of absence for one month, on surgeon's certificate of disability, with permission to apply for an extension, is granted Captain Benjamin Munday, Assistant Surgeon.

First Lieutenant Willian H. Wilson, Assistant Surgeon, is relieved from duty at Fort Leavenworth, Kansas, and ordered to Fort Bayard, New Mexico, for duty at that post.

ORIGINAL ARTICLES.

CLIMATIC CONDITIONS IN THE ROCKY MOUNTAINS FOR THE TREATMENT OF PHTHISIS AND ALLIED AFFECTIONS.

BY ALFRED MANN, M.D.,
OF DENVER, COLORADO.

BROADLY speaking, the whole Rocky-Mountain region offers exceptional advantages in climatic conditions for the treatment of phthisis and allied affections, yet, on comparing different localities in this vast region, it readily appears that they are not all suitable as places of residence for invalids, and that a careful examination is necessary of the elements which together make up the character of any given place before we can safely recommend its sanitary qualifications.

It is not wise without further examination to accept as good evidence the statements of persons interested in real estate and commercial speculations, for these are often notoriously unreliable. Wherever a town or region is being "boomed," there is sure to be loud advertisement of all the various advantages possessed, and of many that are not possessed by the spot in question. The real-estate speculators and settlers discovered early in the history of the settlement of the West that a constant influx of seekers after health, adds materially to the prosperity of the community which they favor with their presence. Hence the chambers of commerce and other public, as well as private, organizations find it remunerative to advertise their locality as "the world's sanitarium," the "Mecca of invalids," etc. Frequently considerable sums of money are spent in such ways that might much better be applied in improving local defective sanitary arrangements.

One of the best advertised towns in the Southwest in this respect is Phœnix, Ariz., and now that another boom has begun in this miscalled health resort, it is time to call the attention of physicians in the East to the difference that exists between a region useful for agricultural and land speculation purposes and one which can properly be recommended for the climatic treatment of throat and lung troubles. The writer having spent four months in winter at Phœnix, and several winters and springs in other parts of the Southwest, considers it his duty to strike a note of warning for the benefit of those who are not so well acquainted with the conditions in that part of the world.

Every one who has had the opportunity of observing a number of phthisical patients for a time after their arrival in Colorado from the East, and has noted the rapidity with which, in a large proportion of the cases, their whole aspect improves, cannot help concluding that there is a tonic effect due to this climate which is far more powerful than that of drugs. This rapid improvement is most noticeable in incipient cases, and, generally, in those in which destruction of lung tissue has not far progressed. But even in cases well advanced in phthisis, an invigorating climate, if not too cold or at too great an altitude, is a material aid to the comfort of invalids. If patients must be sent to Arizona for the winter, why select the most enervating region to place them in, when much better spots are near at hand? Because Phœnix and the Salt-River Valley are productive of fruit and alfalfa, they are not necessarily suited to the purposes of the health-seeker.

The uncritical lay mind argues that, because a certain proportion of cases improve in Phœnix, that town is a good place for consumptives. Every physician knows that not a few cases of tuberculosis of the lungs get well even in New York city, but no one is tempted on that account to send consumptives there for the cure of this malady.

Phœnix lies in the Salt-River Valley, in the southern middle portion of Arizona. The valley has an extent of about sixty miles in length by twenty in breadth. At a short distance below the surface of the soil, at a depth varying, in the neighborhood of the city, from ten to forty feet, there is a permanent lake, one might say, of brackish water. The waterworks of Phœnix are supplied with this water pumped from a well fourteen feet deep, and situated within the outskirts of the city. As the rainfall in Arizona is very scanty, agriculture is carried on by the help of irrigation on a large scale, practically all the water of the Salt River being used for this purpose. The result is that the humidity of the air is comparatively high; in

summer there are regularly heavy dews, and in winter hoar-frosts are far from uncommon.

The town itself, in winter and spring, the only seasons when one would think of sending invalids there, is unhealthful, there being a great deal of sickness, not only among the visitors, but as well among the resident population. This is not to be wondered at when one observes the sanitary arrangements of the place. On both sides of each street run irrigating ditches. These carry running water for several days, and then are empty, with the exception of stagnant pools remaining here and there along their courses, for a period of three or four days more, while the hot Southern sun dries into dust the often noisome filth which covers the bottom. When I visited Phœnix three years ago it was the custom to clean the down-town ditches from time to time, and throw this nasty, ill-smelling black filth into the middle of the street, where the sun rapidly dried it, and the passing wagons ground it into dust and spread it in the air.

There are few cases of tuberculosis benefited in this climate, according to my observations on the spot, in comparison with the number who do well at points farther east in Arizona, in New Mexico, and in Colorado. The climate of Phœnix is depressing, not invigorating. The food and accommodations are very little, if any, better than can be procured in any large town in New Mexico, and are not what they should be for the majority of those who are obliged to seek a warm climate on account of lung trouble.

Phœnix is situated at an altitude of eleven hundred feet only, not enough to satisfy the indication where altitude is desirable in the treatment of tuberculosis. If dryness of atmosphere is desired, it is again far behind many other towns in Arizona and New Mexico.

Unless the streets are continually kept heavily sprinkled the dust is almost unbearable, the soil being chiefly the well-known adobe, which, when dry, forms the finest powder, and is whirled into the air in clouds by every passing vehicle.

The sanitary conditions are better on ranches outside the town, the other factors of the climate remaining the same.

Only in cases with a very weak heart does there seem to be a good reason for preferring the Salt-River Valley to the more bracing climates in the higher districts farther east, and here I am inclined to think that the low desert in the western part of the territory and in southeastern California offers a better, because dryer, climate.

Tucson, Ariz., is about 120 miles Southeast of Phœnix, on the Southern Pacific Railroad. It is more easily reached, and has a far better climate, than the latter town. It is, by comparison, bracing and far more suitable to the majority of cases of phthisis. It has an excellent climate in winter and spring, and is one of the best of the Southern resorts in this respect, though there is some dust, as there is almost everywhere in the Southwest. Unfortunately there is as yet no first-class hotel in Tucson, but fair accommodations can be found. Keeping house is perhaps the most satisfactory way of living. The altitude of Tucson is 2,400 feet.

Forty miles north of Tucson, in the foothills of the Catalina Mountains, is the little hamlet of Oracle. This offers an almost ideal climate eight months in the year for those cases that are too weak to profit by the more stimulating climate of Colorado. It is reached by stage from Tucson in five to six hours, and has several substantial advantages over the towns which, like Phœnix, are situated in the midst of a level agricultural district. Nestling among the hills, high above the valley of the San Pedro River, it is surrounded by unusually attractive scenery, which gives all its walks and drives a perennial charm.

Oracle has no dust, it is even out of range of the dust storms which periodically sweep the whole Southwest. Its altitude is 4,500 feet.

There are several other towns in Arizona and New Mexico which offer a haven for invalids during the bad months. Arizona is sheltered by mountain ranges from the cold northern winds and storms, and is consequently a few degrees warmer than the valley of the Rio Grande in New Mexico. In each territory there are over 320 sunny days in the year, and invalids can spend nearly every day out of doors.

El Paso, Tex.; Las Cruces, Las Vegas, and Las Vegas Hot Springs, of New Mexico, which are close neighbors, have a very good climate, and are annually visited by numbers of health-seekers. Albuquerque and Santa Fé also have their share of visitors.

The elements which together make up the best climate for tuberculous patients are a pure, dry atmosphere, plenty of sunshine, a temperature low enough to be invigorating, and freedom from storms, especially cold wet ones. The effect of altitude seems to be that of stimulating the system, and in cases that have considerable power of reaction the value of this factor may be very great.

All these climatic conditions may be found

combined in varying degrees in the larger part of the area included in Colorado, New Mexico, and Arizona. Everywhere within these limits the number of days on which these invalids need to remain indoors on account of bad weather is very small, as may be inferred from the small amount of rain. The average annual precipitation in Denver for the years 1891, '92, and '93, as given in the reports of the Weather Bureau was 14.97 inches, while for the same years that of New York was 44.45 inches, almost three times as much. In New Mexico and Arizona there is even less rain than in Colorado.

The temperature is never too low to permit an out-of-door life, even in Colorado. The air is dry, except in a few comparatively small areas where irrigation is carried on largely, and its clearness and purity are a perpetual delight to visitors from the east. As we go farther north, the ease with which good accommodations and food are procured steadily increases, and the climate becomes cooler and more bracing.

In conclusion, I wish to offer a few suggestions in regard to a proper selection of climate to suit the various types of cases. Incipient, uncomplicated cases, as a rule, do best in a dry, tonic climate of fairly high altitude. Weak heart, when not due to organic lesion, unless very pronounced, is not a contra-indication for an altitude of 5000 to 6000 feet. On the contrary, as the general health improves, the heart usually grows stronger and the pulse becomes slower.

For cases somewhat further advanced, with breaking down of lung tissue, but otherwise in fair condition, the same climate is useful: that is, high altitude and a cool, dry station. Such a climate is furnished by Colorado. One weighty reason for the selection of Colorado as the residing-place of invalids is the ease with which, in its numerous progressive towns and well-settled rural districts, suitable food and accommodations can be procured. As Dr. Osler says, "In this disease the *prime viæ* control the position," and it is very important that the appetite and digestion should not be interfered with by coarse and unappetizing food. In this respect there is still much left to be desired in most of the resorts of New Mexico and Arizona.

In the case of those far advanced in the course of the disease, with large cavities, etc., it is often advisable, even if not absolutely necessary, that at least the coldest months of the year, say from the middle of December to the middle of May, be spent in a warmer climate free from very cold weather. This can be found in New Mexico, Arizona, and old Mexico. I do not here mention California, for my belief is that the popular and populous parts of Southern California are inferior in value for the purpose under consideration to the dry regions mentioned above.

Cases with organic heart lesion or other serious complication, and those which seem to offer slight resistance to the progress of the disease, are usually better off at low altitudes, and these often bear a fairly warm summer climate quite well. Cases far advanced, with well-marked cavities, high fever, and great general debility, should not, as a rule, be sent from home.

Sometimes it is advisable for a patient to spend the hottest part of the summer in some of the lovely, cool mountain parts of Colorado: the autumn in the altitude of Colorado Springs or Denver, and the winter and early spring in a more southern latitude.

ANTIPHTHISIN.[1]

BY LLEWELLYN P. BARBOUR, M.D.,
OF TULLAHOMA, TENN.;
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS AND LECTURER ON DISEASES OF THE CHEST, MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE SOUTH.

ANTIPHTHISIN is one of the remedies recently introduced for the treatment of tuberculosis. It is the result of efforts to discover a substance that will destroy the germ and directly affect the specific tubercular process.

And this is the claim that its originator makes for it: that it "causes the destruction and disappearance of the tubercle bacillus in living tissue, and the return of the proliferated and degenerated cells to their normal appearance." Notice that the claim for the destruction of the bacilli is in "living tissue" only. A moment's consideration will convince us that this is the limit of any germicide acting upon and through the blood. Bacteria developing in necrotic tissue and caseous masses are not reached by the blood, yet caseous and necrotic areas abound in advanced phthisis. Further, most cases of advanced phthisis have a mixed infection. It is not claimed that antiphthisin will destroy pyogenic germs or directly affect septic processes. Nor can it restore to normal the various degenerations of other organs that are apt to occur in the course of chronic phthisis.

In passing judgment upon any proposed remedy for this disease, we must ever keep in mind these

[1]Read before the Middle Tennessee Medical Association, November 21, 1895.

very varied and serious pathological conditions, and not expect to accomplish impossibilities.

But if antiphthisin will do all that is claimed for it, that is, destroy the tubercle bacilli in living tissue, it will do all we can reasonably expect of any remedy, so far as the purely tubercular process is concerned. If it will do this, we may expect definite and decisive results in tuberculosis of an early stage, and the effect will be more prompt the more vascular the tuberculous area. Even in more advanced phthisis, it is fair, I think, to expect benefit from such a remedy provided the patient has a good degree of general health, with not too extensive areas of caseation and necrosis. In such conditions, we can logically hope to restore the still living tuberculous tissue to health, and thus limit the destructive process; and by continuing the treatment a sufficient length of time, prevent further infection while the caseous mass is being absorbed or otherwise disposed of, and thus eventually bring about a cure.

Now, is antiphthisin such a remedy? Does it actually cause the destruction of bacilli in living tissue and show corresponding results in the treatment of tuberculosis? It is as a contribution to the study of the subject and to help answer this question that I report the following cases.

Before beginning this report, let me say that my patients receive my constant, careful supervision in every detail of their daily lives. I endeavor to guard them against everything that may lower their vitality, and to leave nothing undone in the way of hygienic, dietetic, or therapeutic management that makes for improvement. And while my patients have generally not been able financially to live under ideal conditions, I have endeavored to approach the ideal as nearly as possible in each case.

I was first induced to use antiphthisin by my observations of its effects while I was temporary assistant at the Winyah Sanitarium, Asheville, North Carolina. During the previous year I had been there as a patient, and had excellent opportunity to study the use of tuberculin, and had become painfully aware of its limited field of usefulness, because of its toxic properties. When I returned to assist Dr. Von Ruck during the absence of his house physician, I found that he had very generally superseded the use of tuberculin by that of antiphthisin. And while I still felt, as I had previously written, that good results could be obtained by the careful use of tuberculin in selected cases, yet I was favorably impressed with the antiphthisin as compared with the tuberculin, first, because of its more rapid effect, and second, because of its much wider field of application. Debility and temperature were no bar to its use. During my stay I gave it hundreds of times to patients in all sorts of phthisical conditions, yet I never saw any but very slight toxic effects, though we gave a few doses as large as 8 c.c.

The first case in which I used it in my own work was Mr. K., aged 26, native of Wisconsin. He had had a hemorrhage several months previously, since which time he had been coughing considerably. Sputum about an ounce in twenty-four hours, with few bacilli. Temperature slightly above normal—99½. Pulse and respiration normal. Some tubercular infiltration through entire upper lobe of right lung, indicated by dullness and broncho-vesicular murmurs. Just below the middle of the clavicle on right side there was a little crepitation and a few moist râles. A little lower there was a weak pleuritic friction sound. There was a weakened respiratory murmur in the left apex, but no further evidence of disease.

He received his first dose of antiphthisin December 23, 1894, and continued it one month.

With him, as with all others, I began with $\frac{1}{20}$ c.c. The second day I gave $\frac{1}{10}$ c.c., and increased by $\frac{1}{10}$ c.c. each day to ½ c.c. I kept him on that amount six days, then increased to 1 c.c., and remained on that a few days, and then again increased to 1½ c.c., the amount he was taking at the end of four weeks, when he stopped treatment. At the end of this time he had gained three pounds in weight, and the cough and expectoration had entirely ceased. The adventitious sounds had disappeared, the respiratory murmur had softened, and so far as could be learned by physical examination, the lungs were in a normal condition. His temperature was normal, and he expressed himself as feeling perfectly well. This man passed out from under my observation, and I cannot report his present condition.

Case II.—Female, single, aged 21. She began to lose strength and weight in December, 1894. In January, 1895, she began to cough. The cough was of a hacking quality, with only a little expectoration. Bacilli averaged two to a field. May 3d, she had lost ten pounds in weight, appetite poor, sleep restless. Considerable infiltration was apparent in upper lobe of right lung, extending to lower edge of lobe anteriorly; only in apex posteriorly. In the subclavicular region there were a few râles. At one spot near junction of mammary line with lower border of second rib, there was slight crepitation. On the left side there was a deep-seated spot in the upper part of mammary region of nearly or quite complete consolidation. Just what condition this spot was in, it is, of course, impossible to determine positively, but I concluded it was fibroid tissue, with probably some centres of caseous degeneration.

May 4th, I began the use of antiphthisin, beginning with $\frac{1}{10}$ c.c., gradually increasing, as in all other cases. June 12th, she received 3 c.c., which was repeated on the 13th, 14th, and 15th. At this time, the cough had entirely ceased, the temperature was normal, and the appetite better, though there had been no increase of weight. Dulness less marked, respiratory murmur softened, except at the one place in the upper left mammary region. Râles and crepitation had entirely disappeared. While there was no cough, I found that she did raise a little sputum during a throat-clearing process upon rising in the morning. A microscopic examination showed no bacilli, however. After this I was never able to get sputum to examine from this patient.

Because of the expensiveness of antiphthisin, I now placed this patient on a solution of yeast nuclein, giving it by hypodermic injection, according to directions of Dr. Vaughn, of Ann Arbor. June 17th, she received the first dose of nuclein —8 minims—which was gradually increased to 60 minims on July 6th. While receiving the nuclein, she not only did not improve, but the physical signs grew slightly worse, and the cough reappeared.

July 7th, I resumed the antiphthisin, and between that date and August 8th she received 50 c.c. of the remedy. Under it the cough again rapidly disappeared and other signs improved, so that by August 5th, the date of my last examination, there was no evidence of anything abnormal, except in the one area in the upper part of the left mammary region. The right upper lobe, which gave the most marked evidence of active disease at the first examination, was now apparently restored to a normal condition, but the small spot in the upper mammary region of the left side had improved very little, if any, under treatment.

My explanation is this: On the right side, the tubercular infiltration was recent and the circulation good. The stubborn area on the left side was older, and very probably the seat of primary infection. It had undergone fibroid change, with some centres of caseous degeneration. If I am right, this spot continues as a centre for further infection and a source of danger, and she will ultimately have a relapse, unless the treatment is renewed and continued for a considerable length of time. Up to date, she is reported as holding her own and in fair general health.

CASE III.—Female, single, aged 19. Family history of tuberculosis on the mother's side. A maternal aunt, only a little older than the patient, had died from consumption the previous year. The patient had been very intimate with this aunt, and was with her a great deal during her sickness. Patient had a protracted hacking cough, first in the Fall of 1893. This lasted three or four months and then ceased, only to reappear again in a few weeks. It continued to come and go until October, 1894, since which time there had been no cessation. My first examination of her chest was made in February, 1895. From the physical signs alone, I made a diagnosis of phthisis. The mother, however, refused to believe that her girl had consumption. Some wiseacre of a doctor had told her that the cough was from the liver. Nevertheless, she continued to lose flesh, and the cough increased in severity. In May she began to have some fever each day, and had several slight hemorrhages. An examination revealed a moderate number of bacilli in the sputum.

May 28th, I began giving the patient hypodermic injections of nuclein solution, and continued the treatment three weeks. There was no improvement whatever under the nuclein, and I now persuaded the parents to use the antiphthisin. She was now coughing harder than ever, appetite poor, sleep broken and restless, feverishness and chilly sensations frequent, temperature running to 100 and 100½ each day.

The physical signs were those of almost complete consolidation in right subclavicular region,[1] with considerable deposit throughout upper and middle lobes. On the left side there was only slight trouble in the apex. Bronchial râles and pleuritic friction sounds in right subclavicular region. Between June 24th and August 10th, this patient received 67 c.c. of antiphthisin.

Within two weeks after beginning it, she began to show improvement. By August 10th, expectoration had ceased entirely and the cough almost entirely. She gained eight pounds in weight, with corresponding gain in strength and general appearance. There was marked improvement of all physical signs. In the right subclavicular region there was still some dulness, and the respiratory murmur broncho-vesicular in quality, but much less marked than a month previously, while in the other regions these signs had disappeared. August 12th, this patient married, and has never returned for treatment. She is holding her own still as to weight and general appearance, but has a slight cough. She is not cured, and ought to have continued the treatment a month or two longer.

CASE IV.—Male, aged 32. This patient nursed a brother for several months who had consumption and died in March, 1894. In February, 1895, patient had an attack of "grip," from which he never fully recovered. Since that time, had slowly lost in weight and strength.

June 25th, when he began treatment, patient showed decided tubercular infiltration of left upper lobe. There was a small cavity at the left apex, surrounded with crepitant and other moist râles; broncho-vesicular murmur throughout, extending to lower border of second rib. On right side there were no râles, but there was a loud, harsh, bronchial quality in the murmur with a dull percussion note. Not much cough. Expectoration

[1] A visiting physician, a skilled diagnostician, who saw this patient about the time I began to use the antiphthisin, said that he did not believe it possible to prevent the formation of cavity.

muco-purulent, but scant. Bacilli plentiful. Appetite poor, complexion sallow, sleep restless.

His improvement under antiphthisin was never so rapid as that of case III, but was steady and continuous. By the middle of August his appetite was much better, he was decidedly stronger and he slept better. September 27th, I examined his chest the last time. The râles and crepitation had entirely disappeared. The murmur softened to nearly the normal, except just around the cavity, where there is a fibroid condition. On the right side the physical signs were those of a normal chest, except just above and below the clavicle, where there is a slight dulness and a harsh murmur.

This patient received altogether 150 c. c. of antiphthisin. When he began treatment his temperature was running occasionally to 99½, and sometimes to 100. During the last month of treatment it never went above normal. The bacilli disappeared from the sputum before the end of the second month of treatment and the sputum itself disappeared soon after. He is now attending to business apparently in perfect health.

Case V, male, aged 25. This patient was in an advanced stage when he came under my care, October 5, 1895. There is a large cavity in the apex of right lung, active destructive changes going on in the middle lobe and tubercular infiltration throughout entire lung. On the left side there is considerable deposit in the upper lobe, but slight destructive changes. During the first two weeks of October, he had a high septic fever, his temperature running to 105 and 106 every day. Profuse night sweats followed this high temperature. Although a very unfavorable case, at his request I began the use of antiphthisin on October 11th.

The bacilli are now fewer, take the stain less readily, and show degenerative forms. He is expectorating less freely. There are less râles, and in some places the murmur is clearing. His temperature is now much less, rarely ever going over 101 during the past three weeks. There are no night sweats. While the outlook in his case is not bright, the results have been sufficiently encouraging to lead me to continue the remedy. He is now taking 3 c. c. each day, and has received 47 c. c. altogether. I do not suppose that the antiphthisin is controlling the septic fever directly, but I am sure it is limiting and lessening the tubercular process.

It will be noticed that my patients were all under treatment only a comparatively short time. Cases II and III stopped treatment against my judgment because they felt so well as to think they did not need it longer. Case I was under treatment only a month, yet at the end of this time was apparently a well man. Case II was under treatment three months, inclusive of the time she received nuclein. She improved under antiphthisin, lost ground slightly while taking nuclein, and again improved under antiphthisin. Case III showed no improvement from sixteen days' treatment with nuclein, but gained very rapidly during the fifty days she received antiphthisin, and at the end of that time could not be convinced that she was not perfectly well. Case IV was under treatment a little more than three months. He gained very slowly at first, but steadily, and has continued the gain since.

In each of these cases there has been improvement of the lung condition where improvement could be expected; decided lessening, and in two cases entire cessation of cough. In every case except the last, the bacilli have disappeared from the sputum, and finally expectoration has ceased, while the last case already shows fewer bacilli and lessened sputum. These results are certainly favorable to antiphthisin, and if other competent observers agree with me we must conclude that antiphthisin does actually destroy bacilli in living tubercular tissue, and accord it a high place in the therapeutics of phthisis.

The antiphthisin which I have used has been obtained directly from the laboratory of the Winyah Sanitarium, at Asheville, N. C. For the information of those who would like to know more of the preparation of antiphthisin, I add the following abstract furnished me by Dr. Karl Von Ruck:

"For the production of this curative substance the tubercle bacilli are grown in the ordinary way upon liquid culture media, and when fully developed and matured, the entire culture is treated with kresol, or other germicidal substance, without the application of heat, in order to kill the tubercle bacilli (temperatures sufficient to kill the tubercle bacilli, injure and unfavorably modify the curative substance contained in the culture fluid). After the addition of kresol to the entire culture, the latter is thoroughly shaken, and allowed to stand for twenty-four or more hours.

"Next, the tubercle bacilli are separated from the fluid by filtration. The liquid filtration is now mixed with a solution of sodic iodide of bismuth, or with any other double salt of iodide and bismuth in strong acetic acid, which causes the formation of a precipitate. The sodic iodide of bismuth solution is added so long and in such quantity until no further precipitation occurs from the aforesaid liquid filtrate.

"The liquid filtrate is next made weakly alkaline by addition of a solution of ammonium carbonate or other alkali for the precipitation of the

bismuth salts, under application of gentle heat upon a water-bath with a temperature not to exceed 70° C., and again filtered. The liquid filtrate is next concentrated in vacuum at a temperature not to exceed 70° C., and after concentration is treated with alcohol, under the addition of which a fine grayish-yellow flocculent precipitate is formed, which slowly settles down and adheres to the sides and bottom of the vessel. This is finally collected after repeated washings with alcohol, pouring off the liquid and evaporating any remaining liquid and alcohol at temperatures below 70° C. This last precipitate, obtained by the addition of alcohol, is the curative substance : it is freed by the above process from toxalbumins and other poisonous substances.

"For therapeutic purposes this precipitate is dissolved in distilled water, to which $\frac{1}{5}$ per cent. orthokresol is added for its preservation, forming a clear, yellowish or straw-colored liquid, and it is then administered either by local application or by subcutaneous or rectal injections."

COCAINE-POISONING. WITH REPORT OF A CASE.

BY CHARLES WILSON INGRAHAM, M.D.,
OF BINGHAMTON, N. Y.

DOUBTLESS, at the present time the most frequent source of acute drug-poisoning occurring in the regular practice of medicine and surgery is that following the use of cocaine in legitimate doses or applications. This is due to the increasing, promiscuous use of this drug among the laity for the relief of various affections. Not only is acute cocaine-poisoning of comparatively frequent occurrence, but more danger attaches to poisoning from it than from nearly any other non-corrosive substance.

Though ordinarily possessed of no immediate danger to life, chronic cocaine-poisoning is one of the most unfortunate and pitiable conditions to which human beings are liable. The continuous use of cocaine can scarcely be termed a habit, but rather a moral depravity. In justice to such victims, and in view of our present knowledge of the physiological and later the pathological changes occurring in the body as a result of its habitual use, it is only correct to term such condition *chronic cocaine-poisoning*. The drug produces quite well defined changes in the nervous system, and later in the muscular system. Of recent years many persons have become cocaine *habltués*, or dangerously near that state, from the continued use of some of the so-called "patent catarrh cures." The stealthy, insidious undermining of the nervous system from the regular use of such preparations progresses, until, when the cause is discovered, it is often too late to mend of one's own free will.

A large majority of cases of acute cocaine-poisoning occurring in regular medical practice are due to a peculiar constitutional condition of certain individuals. This condition is generally known as idiosyncrasy. Just what idiosyncrasy is, no one seems to have satisfactorily explained. It is a condition which seems to obtain more frequently and in more alarming proportions from the use of cocaine than from any other drug in common use.

The well-known fact that those who are susceptible to the effects of cocaine are not similarly affected from the administration of other drugs would seem to indicate that cocaine-idiosyncrasy was due to some peculiar *diseased* condition of the individual thus affected. In the healthy individual it is the belief of the author that the use of cocaine in minimum doses or applications, from the hands of regular physicians, is wholly devoid of danger ; that when dangerous symptoms from such doses occur, it is an indication that the health of the subject is considerably below the normal standard.

Cocaine is a comparatively recent drug, and physicians, chemists, and microscopists have not solved many important questions relative to its safe administration. The frequently asserted remark that the action of cocaine is not reliable, that it is unsafe and uncertain, is not, strictly speaking, true. It is the individual to whom it is administered who is unsafe and uncertain. He may have a cardiac, kidney, or nervous affection, either organic or functional, which renders the administration of cocaine in his case, even in minute doses, unsafe. When such conditions are known, or even suspected, cocaine, if given at all, must be administered with great precaution.

It is very possible that suppurative diseases may cause systemic poisoning from absorption of toxins, and so degenerate the heart and kidneys by destructive actio nupon the blood-corpuscles as to render the use of cocaine unsafe. In performing minor surgical operations upon parts of the body where means cannot be employed to prevent its systemic absorption—if the affection is of a suppurative nature and of long standing—it is very doubtful if cocaine anesthesia is justifiable, unless full precautions are taken to prevent or counteract any possible untoward effects.

Cocaine administration in medical practice

could be rendered absolutely safe by refusing its use in persons with kidney and heart affections, and the employment of means which will fortify against the possible occurrence of accidents. How can we fortify against such accidents? First: By the administration of drugs that are known to possess physiological antagonism—morphine and atropine. The physician should administer by hypodermic injection a small dose of a combination of morphine and atropine a few minutes before making use of cocaine. Second: The administration of ten gallons of oxygen gas immediately before making use of cocaine, and having an abundant supply of oxygen gas at hand in case of emergency. It is the author's belief that in oxygen gas we have the only true antidote to cocaine-poisoning.

My interest was first aroused as to the probable benefit to be derived from oxygen gas in the treatment of acute cocaine-poisoning on learning of its marked control over opium and morphine poisoning; and the report of the following case will, I believe, fully sustain the reliability of oxygen gas as an antidote for cocaine-poisoning:

Mr. A., while suffering from a severe attack of toothache, applied to the gums a ten per cent. solution of cocaine by means of pledgets of absorbent cotton. As this process was repeated quite frequently during a whole day and until late in the evening, it is probable that not less than ten grains of the drug reached the system from venous absorption. He, however, noted no unpleasant effects, and retired as usual about 10.30 P.M., but could not get to sleep. About one hour later he noted that the heart action was very rapid and forcible. As the condition seemed to increase in severity, he finally aroused his wife, who at once prepared some brandy, to which was added a few drops of digitalis. This failed to give the slightest relief. At midnight the pulse was 140. It had lost its forcible character, and was soft—almost imperceptible. At 12.30 A.M. patient became unconscious and very delirious. Physicians were immediately summoned, who worked over him faithfully throughout the remainder of the night. Alcoholic stimulants, morphine, and atropine were administered hypodermically. Despite the most skilful efforts the patient continued to weaken, and the comatose condition became more and more extreme. Breathing shallow. Lips blue. Extremities cold. Pulse scarcely perceptible. During the forenoon several additional physicians were called in. The hypodermic treatment was kept up but there was not the slightest reaction, and there seemed no chance whatever of the patient's recovery. At 2 P.M. it was the unanimous opinion of the physicians that he could not survive more than two hours. The lungs were fast becoming congested, and dark clots of blood were occasionally raised. At 3 P.M. the use of oxygen gas was suggested, and a large supply was immediately obtained. Fifty gallons per hour were administered during the following two hours. At 5 P.M., to the surprise of all, the patient showed signs of consciousness, and at 6 o'clock was able to recognize those about him. With the return of consciousness there was a rapid improvement in the general condition. Though he was practically out of danger, his condition remained serious for forty-eight hours. So intense was the general prostration that it was fully one month before the patient was able to be about.

Despite the most skilful and persistent treatment from the hands of the most prominent consultants of the vicinity, there is every reason to believe that, but for the timely administration of oxygen gas, the case would have terminated fatally before the day was over. Considering that the patient had been totally unconscious for fully eighteen hours, and that during this time the symptoms had indicated that recovery was quite impossible, the result cannot be regarded other than remarkable.

There is no doubt that could the experience of physicians with the administration of cocaine be arranged systematically, much of vital importance could be brought to light. Definite rules governing its use could be formulated, and cocaine administration reduced to a scientific basis. The deaths from medicinal doses of cocaine, which are now laid to an indefinite susceptibility, would doubtless be found due to well-defined and preventable causes.

The poisonous action of cocaine seems to assert itself in two distinct ways. First: Collapse of the subject within a few minutes of its administration. This doubtless is the most common action. Second: Several hours following its use, as in the case herein mentioned, showing that it has a cumulative tendency.

This case also suggested the line of action mentioned in another part of this article, for the prevention of accidents from the use of cocaine, as well as for the treatment of acute cocaine-poisoning; and it is the belief of the author that by taking special care to detect contra-indications, and to follow out this line of precaution and treatment, the untoward action of cocaine would be of rare occurrence, and recovery from poisoning from it would be the rule.

A TELEGRAM from Dr. Lapthorn Smith announces that the bullet located by the X-ray in the leg of the patient in the Montreal Hospital was found, on operation, at the exact spot indicated, and was successfully removed

CLINICAL MEMORANDUM.

REPORT OF TWO INTERESTING CASES: ANEURISM OF THE THORACIC AORTA, WITH NECROPSY; ALSO MEDIASTINAL TUMOR, WITH NECROPSY.

By HERMON C. GORDINIER, A.M., M.D.,
OF TROY, N. Y.

PROFESSOR OF PHYSIOLOGY AND ANATOMY OF THE NERVOUS SYSTEM, ALBANY MEDICAL COLLEGE.

Case I.—J. H., aged 48; born in Ireland; occupation, molder. Family history negative, he having no knowledge of his family. Denies syphilis; never has had rheumatism; has been a hard drinker. He is well nourished, stout; height, five feet eight inches. He dates his present trouble back two months, when he contracted a severe cold, accompanied by a violent spasmodic cough, with great dyspnea and the expectoration of large quantities of mucus, but no blood. Three weeks ago he noticed a swelling on right side of neck; a week later observed a marked swelling in right arm, and particularly in hand. His breathing was so disturbed that he was obliged to rest at night in a semi-erect position. For six weeks has suffered with severe, deep-seated pain, beginning in the right shoulder, passing into the infraclavicular region near the sternum and running up the back of the head. Legs never swell; no difficulty in speaking or swallowing; no change in the voice; marked dyspnea on exertion. At times suffers from attacks of violent palpitation; movements of the head bring on severe attacks of dizziness. He is generally cyanosed; has no pain of a boring character.

Physical Examination.—The collar of flesh, so aptly described by Bramwell, well marked. In supraclavicular regions above the middle of the clavicles and extending to their acromial ends, well-marked swellings are observed, which on palpation feel like bunches of veins filling from above. Superficial veins in mammary regions distended, veins of left arm much more distended than those of right. Left arm more edematous. In left lower axillary region a decided sinking inward during inspiration was observed; between fifth and sixth ribs exists a depressed scar, result of abscess from a diseased rib.

Inspection of right mammary and infraclavicular regions over an area the size of one's hand elicited an expansile pulsation, most manifest during suspended respiration. In right infraclavicular and upper mammary regions, between second and fourth ribs, near sternum, is to be felt, on deep pressure, an expansile pulsation. The apex beat is diffused, and covers an area the size of a silver dollar; it is downward and to the left, in sixth intercostal space, an inch outside of mammillary line. During quiet breathing both sides expand equally; breathing short and shallow, respiration thirty-six per minute; on deep inspiration right side seems to move most. Right side is fuller than left; this is particularly true in mammary region near sternum. Despite numerous efforts, tracheal tugging could not be elicited. No bulging in interscapular region. The movements of the vocal cords were normal. Pulse in right radial much less in volume than in left; a decided difference exists in the pulse of the carotids, the right carotid pulse being hardly perceptible, the left full and tense. Percussion.—Dullness over the following territory: beginning an inch to the right of the sternum, at second rib, extending inferiorly to fourth rib, extending nearly to left border of sternum, and on that side as low as the third costal cartilage; longest diameter from right to left, three and a half inches; shortest vertical, nearly three inches. Aortic second sound accentuated over the above area. Faint systolic and diastolic murmurs heard in region of dulness. No episternal murmur; no murmur was heard in the mouth, as is often the case in concealed aneurism. Soft systolic murmur at apex faintly transmitted into axilla. Liver dulness two fingers' breadth below margin of ribs; spleenic dulness normal. No murmur over abdominal aorta; no differences in femoral pulses; no ascites. Respiratory murmur more feeble on right side. Evidence of sympathetic irritation exists; pupils irregular; right pupil dilated; left moderately contracted; right responds sluggishly to light and accommodation, left responsive to both acts. Slight fibrillary twitchings in tongue; reflexes normal; no difficulty in gait. Urine normal; excretion scant.

December 8, 1894.—Patient very cyanotic. Edema of left arm increased; great pain, stabbing in nature under left nipple; dyspnea on the increase; vocal fremitus increased over whole left side posteriorly; dulness in left infrascapular region; crepitant râles, bronchovesicular approaching bronchial; temperature, 100° F.; no expectoration.

December 15, 1894.—Dyspnea great; complete orthopnea; cyanotic to an extreme degree; both arms and legs very edematous. Respiration, 60; pulse, 100, almost imperceptible; collar of flesh more prominent; expansile pulsation more plainly visible.

Patient died December 17, 1894. Autopsy twenty-four hours after death.

Notes.—Rigor mortis well marked. Soft edema of upper extremities more marked on left side; edema of same character in the legs. Neck much swollen. Veins traversing anterior chest wall distended, all superficial veins dilated and full of blood. Muscles soft, flabby and pale, full of serum. Pericardium contained about six ounces of serous fluid. Evidence of old pericardial adhesions on left ventricle and upper part of right. Apex of right lung adherent by tender adhesions, free over rest of surface. Left lung universally adherent, the adhesions being well organized.

Springing from the base of the heart and extending to the right just beyond the junction of the clavicle with the sternum, posteriorly to within one and a half inches of the vertebræ, to the left about half an inch beyond sternal border, and downward as far as the lower border of the fourth costal cartilage, exists a perfectly globular tumor adherent to the sternum and costal cartilages and to the rest of the lungs; the right primary bronchus was found decidedly compressed; the right subclavian artery and the innominate vein were compressed; the right carotid

artery was greatly compressed, leaving but a slight lumen to the vessel. Left subclavian and carotid arteries were dilated and atheromatous. The aneurismal sac was almost a perfect globe, and was filled with laminated fibrin about an inch thick.

Transverse diameter of sac, five inches.

Vertical diameter of sac, six inches.

Antero-posterior diameter, five inches.

The sac arose from the ascending division of the thoracic aorta just above the sinus of Valsalva, the aorta was generally atheromatous, coronary arteries patent, but lumen narrowed from atheroma. Aortic valve thin and papery, aortic opening dilated and incompetent, left ventricle enlarged and cavity dilated, muscle wall firm, mitral valve normal, orifice enlarged. Pulmonary artery filled with an ante-mortem clot. Right ventricle normal as to size, muscle wall soft, pulmonic and tricuspid valves normal. The whole left lung hepatized passing into the third stage. Liver enlarged and apparently fatty. Kidneys undersized, capsules adherent, cortical substance thinned; microscopically they were typically granular.

Case II.—*Case of scirrhus cancer having its primary seat in the tunica adventitia of the aorta.* This case was first observed and demonstrated to my class in medical diagnosis at the Rensselaer County Hospital, November 20, 1895.

May 20, 1895. Mr. E., age 50 years; occupation, grocer. Two years ago had a severe attack of la grippe; recovered perfectly. No history of malignant disease in family.

Present trouble began about four months ago, when he noticed that his health was failing; that he was becoming emaciated, and that he had no desire for food. Eight weeks ago first noticed a severe pain at midsternum, which usually passed backward between the shoulder blades. In a short time began to experience a difficulty in swallowing, particularly solid food. This distress increased until it was absolutely impossible for him to swallow any solids, and at times liquids would distress him severely. Has noticed a gradual increasing difficulty in breathing. Bowels regular. No epigastric pain.

Physical Examination.—Patient short, stout; fairly well nourished; face emaciated; generally sallow. Acne rosacea slightly masked. Chest symmetrical, no local bulgings, no abnormal pulsation, no edema of chest walls or of upper or lower extremities. Veins of chest prominent, those of right side most distended, fill from above. A swelling exists in the inner supraclavicular region near sterno-clavicular junction, which, on palpation, proved to be a mass of movable lymph glands. Liver palpable an inch below ribs. Edge smooth, but very hard and tender. Slight dulness over whole right side posteriorly; respiratory murmur much less distinct than on left side, seeming to be muffled and distant. Vocal fremitus and resonance diminished on right side. Cardiac dulness normal; heart sounds feeble; no adventitious sounds. Splenic dulness normal. Movement of vocal cords normal. Pulse equal, small. 120. Pupils minutely contracted, respond sluggishly to light and accommodation. Reflexes normal. Two distinct splashing sounds on auscultation of the esophagus. Urine normal in amount, sp. gravity 1020; no casts, sugar, albumin, or blood. Blood: 3,000,000 red, 60,000 leucocytes, mostly neutrophiles. Poikilocytosis well marked.

The symptoms taken collectively in connection with the physical signs lead me to diagnose a mediastinal growth probably malignant, which had compressed the esophagus, producing the dysphagia and the double splash heard on auscultation. The distant, feeble respiratory murmur, the diminution of vocal resonance and fremitus as well as the dyspnea, can be well explained by the compressed bronchus. The minutely contracted pupils, which responded but sluggishly to light, were doubtless due to paralysis of the sympathetic with overaction of the motor oculi nerves. The overdistended and greatly dilated chest veins may be explained by compression of the vena cava superior or the vena azygos. I think in this instance, from the location of the principal growth in the posterior mediastinum, from the absence of any enlargement of the veins of the head or neck, that the vena azygos vein was compressed, interfering largely with the intercostal and possibly mammary veins. The malignant character of the growth was suggested by the rapid development of a cachexia, loss of flesh and strength, the enlarged lymph glands; increase in size of the liver, coupled with its very hard and tender border, and lastly, the marked leucocytosis which existed on several occasions.

June 15, 1895.—Progress steadily downward, emaciating rapidly, dyspnea and dysphagia greatly increased, lips and hands cyanotic, pulse soft, small, and rapid, 140; heart sounds very weak; friction rub over left nipple; slightly jaundiced.

June 19th.—Very cyanotic; pulse 160; respiration 60. Patient drowsy, pupils pin-pointed, tongue dry and brown. Expired at 7 P.M.

Autopsy twelve hours after death. Rigor mortis well marked. Slight icteric tint of skin; chest veins dilated and full of blood, panniculus adiposis well marked. Right lung collapsed, left lung held in place by general adhesions. Liver projected two inches below free border of ribs, infiltrated with small and large areas of cancer. Between right primary bronchus and esophagus posteriorly and aorta anteriorly, to which it was inseparably blended, existed an oblong mass about three and one-half inches long and two inches in breadth, which compressed, in connection with a number of enlarged bronchial glands, the right primary bronchus to one-third its natural size. The esophagus was compressed so that it would just permit the introduction of a lead-pencil. Stomach undersized, otherwise normal. Pancreas, spleen, and kidneys normal. No retroperitoneal glands enlarged. Microscopic examination of sections from main mass shows it to be a scirrhus growth, starting, I think, from the tunica adventitia of the aorta, with secondary deposits of a like character in the liver, lungs, and lymph glands.

OBSTRUCTION OF BOWEL BY A LARGE GALL-STONE.

By THEO. G. DAVIS, M.D.,
of Bridgeton, N. J.

Mrs. P., aged 62; a well-nourished, active, hardworking woman, has had during the past three years, several attacks of vertigo, which have been attributed to the effect of a somewhat dilated, irregular heart, or overwork.

During the present year she has had frequent attacks of diarrhea, with so-called bilious symptoms, not severe enough to cause her to consult a physician until September 12, 1895, when, after overworking on a very hot day, she had an attack of vomiting and purging, followed by such prostration that she returned to her home and I was called. I found her with a temperature of 101½° F., complaining of great muscular soreness, especially in limbs and abdomen, with slight retraction of head, somewhat dilated pupils and staring eyes, and a condition of mental apathy, in which answer to all questions was: "I don't know."

Thinking, from the history obtainable, I had a case of spinal meningitis, with involvement of base of brain or perhaps a beginning of rheumatism, I gave aconite, phenacetin, and sodium salicylate. The fever and soreness subsided, and in a few days were gone, but the peculiar mental condition lasted fully two weeks, gradually improved, the patient convalesced, and was about the house as usual.

Owing to trouble and worry she became much depressed, and, five weeks after attack just described, again began to vomit, without purging; a similar mental condition developed; there was no fever: the heart was slower and more regular than usual; she was very restless and had slight soreness and abdominal distress, but no pain even on deep palpation—the soreness was greatest in the region of gall-bladder and head of cecum; at no time was there jaundice, and no itching of skin except when morphine was given to quiet restlessness.

The vomiting, which was at no time stercoraceous, continued for eleven days, during which time there was *absolute constipation*; on the twelfth and thirteenth days there were loose movements; on the fourteenth a great desire for stool, which was ineffectual.

Examining the rectum I found a hard, movable body, which, when removed by stretching the sphincter, proved to be an ovoid cylindrical gall-stone, measuring in its least circumference 3⅞ inches, and in its greatest circumference 4¼ inches, and weighing 265 grains.

The patient made a gradual recovery.

Reviewing the case, I think at the first attack the gall-bladder ulcerated and the stone passed into the duodenum, slowly making its way through the small intestines; until reaching the ileo-cecal valve it caused complete obstruction, lasting eleven days, and during the next two days reached the anus.

The mental symptoms were doubtless caused by auto-intoxication.

REPORT OF A CASE OF PERFORATIVE PERITONITIS FROM A FOREIGN BODY IN COLON ASCENDENS.

By K. HOEGH, M.D.,
of Minneapolis, Minn.

E. S., male, age 43; brakeman on a freight train; had always enjoyed good health and been of good habits, when he, about the middle of December, 1895, began to make occasional complaints of griping pain in abdomen; he continued to work, and took no medicine. December 27th or 28th the pains were worse, so that instead of going out on his train he remained at home, and did not resume work before the 11th of January, 1896. While at home he did not go to bed or consult a physician, but took various saline cathartics, without, however, getting what he considered an adequate response from them. He worked on his train to 17th of January, when he was taken severely ill with abominal pain. He consulted a physician at the place where his train was at that time, upward of two hundreds miles from home. He came home the next morning in some pain, unable to work; went to bed, where I found him about noon the 18th. He was suffering from quite severe colicky pains; had had some very small passages after enemata, without relief of the pain. Since the previous day he had vomited whatever he took into his stomach, first food, and afterward water, which he occasionally had kept down for half an hour. It had a greenish color, and was mixed with some grumous, blackish shreds: its exact character could not be determined; it had no fecal odor. In the intervals of pain he had a placid expression, but at times his features and bearing would indicate great suffering. He would get out of bed, bend over, and groan. Abdomen was slightly distended; in no region was there any considerable tenderness upon moderate pressure; but deep pressure was disagreeable to him everywhere, most so above the navel, and behind in the right lumbar region; no tenderness over the seat of the appendix; none in the region of the gall-bladder; none over the stomach. Tongue moist and clean, temperature 99, pulse 60, respiration 22. Treatment consisted in a warm, moist application to abdomen, and enemata of asafetida with opium. He passed a bad day, and a worse night, the colicky pains continuing; vomiting however became less frequent. The 19th the temperature was 99.2, pulse 52, respiration 20, abdomen distended a little, tenderness the same as previous day, viz., some in right lumbar region, and some around the navel, more marked on right side. Tongue remains moist and clean, and his general aspect good, between the cramps; morphine administered hypodermically. On the 20th the condition was very much the same; his urine was found clear, acid, sp. gr. 1022, free from albumin and sugar, and no indican; temperature 98.3, pulse 56, respiration 21; tongue moist and clean. He had had no passage by the bowels, but vomiting had ceased. During this day, however, a sudden change for the worse took place. Dr. A. Barnes saw him in the evening, found abdomen quite tympanitic and tender; he was able to demonstrate the presence of free fluid in the abdominal cavity; tenderness well marked, most so around the navel;

liver and spleen dulness abolished. The bowels had not moved, and vomiting of a grumous fluid had taken place twice during the day—temperature 101, pulse 70. On the 21st he was found in very much the same condition as the previous night: his dyspnœa was more marked; there had been no movement of the bowels, but vomiting had ceased. His tongue, which had become dry the previous day, remained so—his features indicated collapse;—temperature 101, pulse 100. A 3 o'clock in the afternoon a consultation was called, and Drs. David Thomas and A. Barnes saw him with me. An examination of rectum proved only that the intestine was empty. He was now so weak, with a pulse of 124 and dry tongue, that a laparotomy was considered unjustifiable. While the presence of general peritonitis seemed evident, it was impossible for us to reach any conclusion as to its cause: it could not well be from any inflammation of the appendix, for the local tenderness at the characteristic point was absent; nor does appendicitis usually run a course beginning with afebrile colic with free intervals. Hepatic colic was also ruled out as a probable explanation; nor could it be a gastric ulcer, although such ulcers may run a latent course and reveal themselves by a sudden perforation. A suspicion was entertained that the case was one of acute pancreatitis, although this disease is not usually afebrile. It had been this very uncertainty in the diagnosis, which had prevented an early laparotomy, when it might have seemed advisable. About midnight the 21st he became delirious, and died at 4 A.M. the 22d. A necropsy was held the next afternoon by Dr. Palmer Findley, in the presence of Dr. A. Barnes and myself. Only the abdominal cavity was opened, as the family had reluctantly given their consent to the necropsy. The bowels protruded very much, being distended by gas; they were of a glistening, pale appearance, not injected, not covered by lymph or pus; some fluid was seen in the flanks, a strong fecal odor was observed, the cause of which was immediately apparent by the escape of gas in bubbles, mixed with minute particles of feces, which came out through three very small, hardly visible openings in the colon ascendens at a place where it was loosely agglutinated by recent adhesions to a coil of the small intestine, about three and one-half inches from the ileocæcal valve. In one of these holes there was sticking out for about one-third of an inch the sharp point of a Japanese toothpick, which was extracted and found to be bent by a "greenstick" fracture, so that the thick end formed a very acute angle with the pointed end. It seemed, also, that this end had engaged in one of the minute openings, lying close to the one through which the pointed end projected. Upon trying to separate the adhesions a large hole was accidentally torn in the adjacent part of the colon ascendens, and feces ran out, contaminating the fluid in the iliac fossa which had seemed to be clear. The cecum was lifted out; it was very much distended by thick pultaceous masses of feces, in which undigested (or partly digested) grains and some coarse, finely minced fibers (cabbage?) were discovered. The appendix was healthy; the inner wall of cæcum was somewhat congested, its outside wall apparently healthy up to near the place in the colon where the perforation had taken place, where there was a small area of deep purple ecchymosis. The ascending colon showed only the aforesaid small holes, now united into one. The remainder of the intestinal canal appeared perfectly normal, pale, and with whole and healthy mucous membrane. The appearance of the stomach, liver, gall-bladder, pancreas and mesentery was normal.

Taking the history of the case and the post-mortem appearances together, it seems fair to attribute the perforation of the bowel to the toothpick. The griping pains, five weeks before death, may have been produced by the point of toothpick engaging in the mucosa; injudicious purging producing violent peristalsis pressed the toothpick further in; probably a minute suppurative focus was established, surrounded by adhesion to a neighboring coil; the violent muscular efforts incident to his occupation tore the adhesions, and a localized peritonitis took place around it of an agglutinative character; but this was overtaken by a destructive necrotic process, which finally brought about perforation into the general peritoneal cavity. There were several ways of interpreting the mild previous peretonitis, and I did not feel justified in undertaking an operation which, if it had not revealed a removable cause, might have been severely criticized. It is a precarious matter to perform a laparotomy when it is not possible to make even a probable diagnosis.

MEDICAL PROGRESS.

Rupture of the Uterus, with Recovery.—Queisner (*Centralbl. für Gynäkologie*, 1895, No. 51, p. 1341) has reported the case of a woman, 38 years old, who in the course of her ninth labor experienced a sense of something having torn in the abdomen. The pains, which previously had been active, suddenly ceased, and the woman lost consciousness and presented the appearance of collapse. External examination showed the breech to be above and the head at the superior strait; the small parts could not be detected. On introducing the hand into the dilated os a uterine laceration, between four and five inches long, could be felt at the right side of the fundus, in which rested the right lower extremity of the fetus, which projected into the peritoneal cavity through a tear two inches in extent. The umbilical cord was pulseless. The right foot was carefully drawn into the uterus, and version readily effected. The placenta was seated upon the anterior uterine wall, and was removed by the hand. After the removal of the fetus the uterus contracted well upon the left side, the right half remaining relaxed and boggy. The pulse was improved by injections of ether. The hemorrhage was slight and tamponade was unnecessary. A five-pound sand-bag was placed over the uterus, a bandage applied, and opium administered. The woman was out of bed on the fourteenth day. After the lapse of four months the uterus was anteverted and displaced to the right. Upon the right side a firm, sensitive cicatrix could be felt. Five months later the cicatrix could still be appreciated, but the sensitiveness was less. The only predisposing influence to which the rupture of the uterus

could be related was the lifting of a heavy weight, as there appeared to be no disproportion between the uterus, the fetus, and the uterine contractions.

Acromegaly Complicated by Posterior Sclerosis.—At a meeting of the Medical Society of Hamburg, NONNE (*Deutsche medicin. Wochenschr.*, 1895, No. 4, Suppl. No. 3, p. 14) reported the case of a woman, 41 years old, without hereditary predisposition, in whom there had been present for three years, following labor, symptoms of acromegaly. The thyroid gland was not appreciable, and there was no dulness on percussion over the sternum. The visual fields were normal for white, but contracted for colors, upon the right in greater degree than upon the left. Visual acuity was lessened, in consequence of beginning optic atrophy. The pupils were contracted and reacted imperfectly to light-stimulus and in accommodation. The knee-jerks were wanting, and lancinating pains were present in both lower extremities. There was no ataxia, no impairment of sensibility, no paresis, no derangement of the function of the sphincters, and no tenderness on pressure on nerves or muscles.

The Nervous Complications of Erysipelas.—CROCHET (*Thèse de Paris*, 1895; *Rev. des Sc. méd.*, 1896, No. 93, p. 161), in a collection of 597 cases of erysipelas, found nervous complications in 53. Among these were syncope at the onset; delirium (independently of involvement of the scalp), meningitis, enfeeblement of the sphincters, choreiform movements at the height of the disease; and during convalescence vertigo, visual disturbances, amaurosis, paralysis of the oculo-motor nerve, paralysis of the extremities, pseudotabes, symmetrical gangrene of the extremities sensory, disturbances, auditory disturbances, and neuralgia. In those predisposed it was found that erysipelas may excite neuroses such as hysteria, and exceptionally psychoses such as general paralysis. These complications are to be attributed to the action of the toxin of erysipelas upon the nervous structures, as demonstrated experimentally. The possibility of secondary infection must, however, not be ignored, as pneumococci, alone or associated with streptococci, have been found in the exudate present in a case of meningitis, complicating erysipelas. The various nervous complications noted usually terminate in recovery.

Ascending Degeneration of the Pyramidal Tracts in a Case of Transverse Syphilitic Myelitis.—DEJÉRINE and SOTTAS (*Archives de Physiologie*, 1896, No. 1, p. 128) have reported the case of a man, 67 years old, who at the age of 30 years had a chancre followed by manifestations of secondary syphilis. Four years later he suffered from transient weakness of the legs, and a year after this from sudden transitory paraplegia predominating in the right leg, with retention of urine. This condition grew progressively worse for two years, and then remained stationary. At the age of 62 the man presented spastic paralysis, the more pronounced upon the right, with unimpaired sensibility, with enfeebled sphincters, and with muscular atrophy of the right side of the body. Three years later there was an aggravation of the condition, with wasting of the legs, impairment of sensibility, and incontinence of the sphincters. Cystitis and bedsores developed and led to a fatal issue. Upon post-mortem examination, brain, spinal canal, and soft membranes were found intact. In the mid-dorsal region of the cord, however, there existed the remains of a transverse inflammatory lesion, microscopically presenting the appearances of a syphilitic meningo-vasculitis. There had evidently been disseminated softening followed by sclerosis of the nervous structure of the cord, particularly in a segment included between the fifth and the ninth dorsal roots. Ascending degeneration of the postero-median columns and of the direct cerebellar tract had taken place and descending degeneration of the pyramidal tracts: but, strangest of all was an ascending degeneration of the anterior and later pyramidal tracts.

THERAPEUTIC NOTES.

Thyroidtherapy as Applied to Psychoses Associated with Goitre.—REINHOLD (*Munchener medicin. Wochenschrift*, 1895, No. 52, p. 1205) reports a series of interesting observations showing that the administration of fresh thyroid gland or dry extracts of the gland to individuals suffering with psychoses in association with parenchymatous goiter, while followed by pronounced diminution in the size of the enlarged gland, is unattended with any influence upon the mental state. On the other hand, the medication also occasioned no unpleasant effects.

The Prophylaxis of Acute Articular Rheumatism.—On the hypothesis that acute articular rheumatism often arises by infection through the pharynx STEKEL recommends the employment of a gargle containing citric acid in all cases of pharyngitis and tonsillitis of rheumatic type.

Take of

Citric acid	2½ drams
Water	3 fluid ounces
Saccharin	6 grains.—Mix.

Dose: Add a tablespoonful to a glass of water, and use frequently as a gargle, swallowing a mouthful.

For infants, less than a year old, the following formula is recommended:

Take of

Citric acid	15 grains.
Water	2 fluid ounces.
Syrup of Lemon	1 fluid ounce.—Mix.

Dose: A teaspoonful every half-hour.

—*Médicine moderne.*

For Uterine Leucorrhea.—

Take of

Tannic acid	2 ounces.
Pure alcohol	1 fluid ounce.
Beechwood creosote	1 fluid ounce.
Distilled water	8 fluid ounces.—Mix.

Dose: A tablespoonful in a quart of warm water, to be used as a vaginal injection, three or four times a day.

—LIROLA, *Semaine médicale.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

POSSIBILITIES OF THE ROENTGEN RAY IN MEDICINE.

Now that the early excitement created by Röntgen's announcement of his discovery has partially subsided, the reflecting men of the scientific world, as well as the profession, are beginning to eliminate the visionary speculations that at first suggested themselves, and determine the definite directions in which the X ray can be of practical value. We have now sufficient information as to its real nature and present limitations to enable us to form a fairly reasonable and definite estimate of what we may hope from it in our own particular field.

Let us consider, then, in the first place, what we have discovered that it will not do. The wild fancy that this power was a peculiarly penetrating form of "vision"—a sort of photographic second sight or "materialized eye"—which could be caused to calmly penetrate to just such depths of the human tissues as the operator desired, and reproduce a complete picture of everything it found at that particular level, is far from the truth. The well-known statement of the charlatan to his gaping patient, "I've been looking at your kidneys, sir, for the last ten minutes, and they are badly shrivelled, sir, badly shrivelled!" is not to be literally realized. Unfortunately for our antivivisection friends, it must be admitted also that the early hope inspired by this power that we should thus be enabled to watch the various functions of the internal organs of the body, and so render vivisection unnecessary, is fast fading into the baseless fabric of a dream.

The futility of such speculation becomes promptly apparent when we recall the fact that this new picture is not a photograph at all, but simply a shadow or silhouette, so that no details whatever, except as they depend upon density and thickness, can be reproduced. Indeed, the term photograph is doubly inappropriate, since it is not light rays at all that are concerned in the process, but, as we pointed out in our last issue, certain totally invisible vibrations given off in electric incandescence. These, from their being as yet a literally "unknown quantity," have been (according to the painfully familiar formula of our schoolboy days) termed by Röntgen the X ray, and Schubert, of Hamburg, actually proposes the term "xograph" for their product and "xing" for the process.

It will be remembered that Prof. Goodspeed in our last issue suggested *radiograph*[1] and *radiography* as appropriate terms, and Dr. Cattell coined the words *skiagraph* and *skotograph*.

As far as our present knowledge goes the positive advantages to medicine seem to be limited to three conditions: fractures, dislocations and tumors of bones, encysted bullets, needles or pieces of glass in the tissues, and earthy calculi. In the first class of conditions its advantages would appear to be slight unless great advances upon present powers and methods can be made. The *tactus eruditus* is certainly a delicate and reliable sense in investigating fractures and dislocations, and it is questionable how much help can be obtained by such crude and blurred shadow pictures as can at present be obtained. In recent cases of fracture or dislocation, the delay and discomfort to the patient necessarily involved in the

[1] Dr. A. Rose writes that *radiograph* is ahybrid word, *radius* being Latin and *graphe* Greek, and hence is an unfortunate suggestion.

application of the method would be practically an insuperable objection to its use for purposes of diagnosis. This objection, however, has been met by the instrument[1] for visual use, invented by Prof. Magie, of Princeton.

As a means of ascertaining that the parts had been placed in proper position after adjustment, it would, however, be most valuable, for of course all splints and dressings, except plaster or metallic splints, would be as "translucent" as the soft tissues themselves. Its principal value, however, would be in obscure cases with much swelling, "green-stick" fractures for instance, in partial luxations, and in medico-legal cases when the proper setting of a fracture or reduction of a dislocation was in question.

In the locating of bullets, some brilliant results have been already recorded, in which the bullet, beyond the reach of touch or probe, has been found by the X ray and successfully removed. It might not be out of place here to call attention to the fact to which Prof. Bergmann, of Berlin, has alluded, that a bullet successfully encysted in the tissues becomes a harmless body, and the danger now arises that every one who has been carrying bullets, needles, and shot for years, without harm to himself, will be possessed with the passion to have them located and dug out. Against this, Prof. Bergmann protests as being dangerous and unnecessary. It must be remembered that as a rule it is the tract through which the bullet has plowed that is the source of danger, and not the missile itself.

In locating renal and urinary calculi, the Röntgen method will be of great value, although of course only as an aid to the sound in the more obscure cases. And Nüsser, of Vienna, has already used it with success in demonstrating the presence of a stone in the pelvis of the kidney. It is not yet known whether gall-stones are sufficiently opaque to be detected by its rays.

So far as present developments have gone, Hamlet's ardent aspiration, "Oh that this too, too solid flesh would melt," has been so completely fulfilled that not a trace of any of the soft tissues of the body remains, except a light haze, even the articular cartilages being so completely penetrated that the bones appear entirely separated from each other at the joints.

One interesting and important field of investigation remains to be considered; and that is the effect of the X ray upon germ life. It is a well-known fact that sunlight possesses a decidedly germicidal effect, and that if the prismatic rays be passed through a culture-tube containing a fluid medium, the various bacilli therein will exhibit a selective action. And it has occurred to more than one worker along the lines of bacteriological investigation that it was quite within the realm of possibility that the Röntgen ray would be found capable of killing bacteria within the human system.

During the past week, in order to test the influence of the Röntgen rays upon germ life, pure cultures of diphtheria bacilli were obtained from Dr. W. H. Park, of the Bacteriological Laboratory of the New York Board of Health, and subjected to the direct effect of the rays from a Crookes tube for thirty minutes. Cultures were made both before and after the exposure which were personally developed in the laboratory by Dr. Park, who reports that no effect whatever was discovered to have resulted from the exposure. It is therefore only possible to announce one experiment, with negative result, while the investigation is being further pursued along the same and parallel lines.

[1] This is described in the MEDICAL NEWS of February 15th.

THE MEDICAL CORPS OF THE NAVY.

THE report of the surgeon-general of the navy for 1895 called attention to some very important, even startling, facts, in which not only the well-being of the corps is concerned, but the entire profession of the country as well. It appears that the corps, when full, numbers 170 men; that a medical examining board is constantly in session, but that for a number of years sufficient material has not appeared to fill the list, and, moreover, that of the nineteen who came for examination the past year to fill the large number of vacancies, only four were found competent, though the examination is one in which a man of ordinary capacity has no good excuse for failure.

It will be remembered that our navy has many new and splendid ships; that these are often in foreign ports, where many opportunities for cul-

ture and improvement must offer; also that shore duty is usually in or contiguous to great cities, with all the advantages which accompany such residence. Why is it, then, that the medical corps of the navy is so unpopular and so little in favor with the profession that it alone, of all the branches of the public service, is unable, year after year, to obtain its full complement of men?

The first objection which appears is an insuperable one, because it affects the dignity and self-respect of every man who offers himself to the service. It seems to be based upon the feeling among officers in other branches of the navy that the profession of medicine is inferior to the profession of arms; otherwise, why is it that the medical officer who begins his service, who also, by the way, must begin in a grade lower than in the medical service of the army, is at once placed on a lower social plane and with conditions inferior to those of his fellow officers—that is, he cannot mess with others of his profession on board ship—he must sleep on a bunk in the steerage, and for three years he must lead the steerage life. We can hardly imagine anything more depressing or humiliating to a young man of spirit and ability than such treatment, and we wonder that any one can be found who will accept service under such requirements. It is the melancholy fact that the United States is the only country having a navy of any importance in which the medical service is subjected to such indignities.

The law as to the retirement of medical officers in the navy seems most inequitable. The army medical officer can retire after thirty years of service, the naval medical officer only after forty; and, as the circumstances of his education, which, be it observed, is always obtained at his own expense, in distinction from the line officer, who is educated by the government, as these circumstances compel him to enter the service at least five, and perhaps ten, years later than the line officer, the latter is given a distinct advantage. In the English navy, medical officers may retire after twenty years of service. The titles, which, in the public service, always seem to excite more consideration than common sense would dictate for such conditions, are also to the disadvantage of the medical corps. It is possible that this will be remedied, if the bill for reorganizing the medical corps of the navy, now before Congress, shall be passed. The titles proposed under the new arrangement are: medical director and medical inspector (the same as at present), staff surgeon, surgeon, and surgeon of the junior grade. The regulations concerning medical officers are also inequitable with reference to rank. For example, a surgeon has the relative rank of a lieutenant or a lieutenant-commander. Furthermore, the rank of the medical officer, at least in the lower grades, is made to depend upon the conditions affecting the rank of members of the same grade in the line, a medical officer having what is known as his running-mate in the line, and his rank not increasing until that of his running-mate has increased.

If we have a correct understanding of this regulation, it becomes a matter of astonishment that such a stupid and unjust custom has been allowed to come into being—still more to persist. An officer is refused promotion, not because he has not served long enough or faithfully enough, but because promotion has not come to a co-ordinate officer in another branch of the service. We are amazed that a sense of justice should allow such partial and unfair regulations.

As a further evidence of the estimation in which the medical corps is held, it is proposed to degrade the rank of the surgeon-general from commodore, in case that grade is abolished, to post-captain, while the commodores in all other branches of the service are to be promoted to rear-admirals.

The foregoing statements are authentic. It is surprising, in view of such facts, that there is any medical corps at all, that men can be found, sufficiently capable to retain position, with such disagreeable comparisons and such odious customs constantly to be submitted to.

The medical profession asks no odds of the profession of arms, or of any other, in point of dignity, learning, and usefulness. Whatever it may have been in the past, there is now no difference of opinion on this point among those whose opinion is really valuable. If it is the policy of the naval authorities, not only to withhold adequate inducements to men of ability to enter the medical corps, but to snub and humiliate those whom they do receive, they need not be surprised

if the quality obtained corresponds to the conditions, nor that in some grave emergency, when, like pistols in Texas, the services of accomplished men are sorely needed, the question of accountability will come back upon them to plague them.

It is apparent that, however efficient our new ships may be as fighting machines, they are greatly lacking in such matters as pertain to the health and comfort of those who work them. Think of working in a fire-room for hours at a temperature of 130° F. or more. The sick-bay, on the other hand, may have a temperature considerably under 70°, and be dark and stuffy, and entirely unsuited to the wants of the sick. The difficulties of getting the wounded from the decks into the sick-bay in time of action, and hundreds of other questions in our modern navy, have to be decided by the members of the medical corps.

We know that Jack ashore, as well as Jack at sea, has a wholesome contempt of drugs. Fortunately, he doesn't usually require many, irregular though his life may be, and perhaps it is his dislike for medicine in general which has been the foundation for the ill treatment of the medical corps. The sailorman, high and low, however, should understand that there are many conditions in addition to that of dispenser of medicines, for which it is essential that a skilled doctor should be on board ship and in a naval hospital. That being the case, it should be our aim and pride to attract only the best and most efficient men who can be found—men who will compare favorably with the best in every other branch of the service.

With all the inducements that are possible, it may still prove to be true that those who are most to be desired will not enter the naval service.

Under any circumstances, the opportunities for distinction as physicians or surgeons can never be very great. They can never be as great as in the army. As sanitarians and hygienists, the naval medical corps has many interesting problems to work out in hospital and on board ship. In that direction they should bend their efforts to gain honorable distinction. Such questions as the hygiene of navy yards, the high development of naval hospitals, the preparation of litters and other appliances for removing those who are wounded in action, the ventilation of ships, the sick-bay and operating-room on board ship, the ambulance ship as tender to a fleet, etc., are all questions which are more or less unsolved, and are worthy of the best thought.

But the first step toward having an efficient medical corps is to make the conditions and surroundings such that no self-respecting man need hesitate to accept them.

BACTERIOLOGY.

COMMMENTS ON SOME OF THE OBJECTIONS OFFERED TO THE USE OF ANTITOXIN IN THE TREATMENT OF DIPHTHERIA.

THE failure of tuberculin to realize the beneficial results hoped for has frequently been advanced as an argument against the use of diphtheria antitoxin. Except in so far that the tuberculin excitement showed that too many physicians were fallible and too prone to adopt a treatment before it had been carefully tested, the failure of tuberculin as a therapeutic agent has no bearing on the value of diphtheria antitoxin. Tuberculin is properly compared with diphtheria toxin, or poison, they both being the products of the growth of specific bacteria in nutrient media.

Diphtheria is a self-limited disease, because, in part at least, the reaction of the tissues to the toxin produces an antitoxin. Tuberculosis as a rule, is not self-limited, and up to the present time we have not obtained a substance which is antitoxic to the products of the tubercle bacillus. In all animals we find the poisonous effects of the toxin produced by the bacillus of human diphtheria to be entirely neutralized by sufficient amounts of antitoxin, if it is given before the animals are profoundly affected constitutionally. Tuberculous animals, on the other hand, are killed by injections of sufficient quantities of tuberculin.

Animal experiments gave us, therefore, firm grounds for hoping that the serum would be antitoxic for the same poison in men that it was in animals. Whether in actual experience we would meet with diphtheria early enough to get these beneficial effects, only experience in actual cases of human diphtheria, not animal experiments,

could determine. Now, after three years of ever-increasing use, the men who have had the largest experience, are almost universally of the opinion that diphtheria antitoxin has marked curative power in diphtheria, and that many who are now alive would have died without its use.

A misconception concerning the effects of the use of bacterial cultures in swelling the number of cases called diphtheria, and indeed of the meaning of the results obtained from cultures, seems surprisingly prevalent.

The detection of the diphtheria bacilli in a culture from the throat proves that the throat from which it was made is infected and is a possible source of contagion. If no disease is present, it would be ridiculous to assert that the patient had diphtheria. If, on the other hand, exudate is present, the probability that that exudate is caused by the diphtheria bacilli becomes so strong as to amount almost to a certainty. As a matter of fact, in New York at least, the majority of suspected cases are proved by cultures not to be diphtheria. I believe, however, that the added interest in diphtheria at the present time causes a somewhat greater proportion of mild cases to be reported than formerly, and that for this reason percentage statistics may appear in cities to show a somewhat greater apparent reduction in the percentage mortality than is correct. There is, however, in addition to this, a marked reduction in the actual number of deaths in those cities where antitoxin is extensively used.

The results reported from the Willard Parker Hospital by different men have had a very confusing effect upon the profession, and very frequent inquiries have been made concerning them. The hospital records show the following numbers of deaths and recoveries during January of the last three years:

	Recovered.	Died.	Mortality.
January, '94, no antitoxin.	32	21	39.6 per cent.
January, '95, very weak antitoxin; temperature in wards 80–85°. .	36	15	29.4 per cent.
January, '96, very strong antitoxin; temperature in wards, except for four days, 70–75°. . .	54	13[1]	19.4 per cent.

[1]Four of these deaths occurred in persons not receiving antitoxin; two because they refused it, and two because they were moribund on admission, one dying in ten minutes.

The large number of cases of laryngeal diphtheria admitted during 1895, who after the removal of the tube appeared for the time to be doing well, only later to develop a subacute broncho-pneumonia, was indeed most discouraging.

It is true that a larger proportion of cases finally got well than in the previous year, and that the very prolongation of life in those finally dying of pneumonia showed some new and powerful influence was at work. To the children, however, it was the same whether death came early or late.

The cause of this broncho-pneumonia was carefully searched for by the physicians connected with the hospital.

It was found that the wards were somewhat crowded, and also that for certain theoretical reasons the temperature was kept in the acute wards at from 80° to 85° F. The crowding was lessened, and with the year 1896 the temperature was lowered to 70°. Since then no broncho-pneumonia has developed in any case which was not present on admission, and the results have been most favorable.

During the twenty-six days of January when the temperature was kept at 70°, nine cases were admitted requiring intubation. One of these cases, an adult, admitted on the second day of her disease, refused to take antitoxin—she died. Of the other eight cases six recovered. One of the two fatal cases, who received antitoxin, died in sixteen hours, and the other later after the development of a complicating measles. This certainly is a favorable showing, for not counting the death of the case admitted upon the second day where antitoxin was refused, there were six recoveries in eight cases. The cases admitted up to the present time continue to do remarkably well.

Only two persons who had diphtheria of any severity refused antitoxin. They both died. One of these admitted on the second day of the disease with laryngeal diphtheria was intubated the day after admission, and died the following day of heart-failure. The case was very severe from the outset. The other, a child of 13 years, admitted on the third day with well-marked pharyngeal diphtheria, died five days later of

heart-failure. I have not seen such a case die under the antitoxin treatment.

The results of the use of antitoxin in Chicago, a report of which is published in this number, show the favorable results obtained there with antitoxin, prepared in the same laboratory that furnishes that used in the Willard Parker Hospital.

At the recent dinner of the Boston City Hospital Club Dr. J. H. McCollom gave an account of the results obtained with antitoxin in the department of that hospital for contagious diseases which are also most favorable. He said in part:

"Since the department was opened on August 31, 1895, there has been 844 cases of diphtheria admitted, with 96 deaths, giving a mortality of 11 per cent.

"All of these cases have been treated with antitoxin, and the result is certainly remarkable.

"If we compare this death-rate from diphtheria of 11 per cent. since the introduction of antitoxin, with that of a death-rate in the hospital of 40 per cent. before the introduction of antitoxin, there can be but one opinion regarding the efficacy of the remedy. The effect of antitoxin in the operative cases has been very marked. In the report of the Boston City Hospital for the year ending January 31, 1895, before antitoxin was generally used, there were eighty-six cases of intubation, with seventy-four deaths, giving a mortality of 86 per cent. In the south department from August 30, 1895, to February 1, 1896, there seventy-nine intubations, with thirty-six deaths, giving a percentage of 45, a diminution of nearly one-half.

"The change in the appearance of diphtheria wards, since the introduction of the use of antitoxin, has been very marked. In making a visit one cannot help being struck with the bright and cheerful appearance of the children."

The latest results when grouped together seem to me to clearly indicate: that with serum strong in antitoxin, and with increased experience, we may hope to save very many lives by the early use of antitoxin. Until we can entirely eliminate the horse serum we will indeed have occasional disagreeable after-effects, but these will be rarely, if ever, of a dangerous nature.

William Hallock Park, M.D.

ECHOES AND NEWS.

The Rontgen ray has found rather an unexpected application in archeology. It turns its attention to the mysteries of the past as well as the present. For instance, Harold Fredricks, in the New York *Times* of Sunday, February 16th, announces that the Vienna Museum for some time has possessed as its chief treasure an Egyptian mummy, which is swathed to resemble a human being, but the inscription on which suggested it to be an ibis instead. The thing was too rare and precious to run the risk of unwinding its bandages to solve this problem, but the shadow photograph now plainly reveals the skeleton of a large bird.

Mr. Frederick M. Shepard, of East Orange, N. J., has given $10,000 to the Orange Memorial Hospital, for the construction of a pavilion for consumptives.

It is noticeable that on the Board of Managers of the Manhattan State Hospital for the Insane recently appointed by Governor Morton, are two women, Eleanor Kinnicutt and Alice Pine.

William Cæsar, a negro who had been convicted of murder, and was awaiting in Sing Sing, N. Y., the execution of his sentence, died in prison from edema of the lungs and glottis. Necropsy revealed evidences of former meningitis in a number of places with adhesions to the brain.

Recent advices from Wisconsin report a fresh outbreak of smallpox. Three cases have developed in an industrial school for boys at Waukesha, which contains between three and four hundred inmates.

Steps are being taken to organize an association of Western eye, ear, and throat specialists. A preliminary meeting has been announced for April 7, 1896, to convene at the Midland hotel, Kansas City, Mo.

Philadelphia is soon to have a large office building devoted exclusively to the use of physicians, to be known as "The Clinic." Cincinnati and New Orleans have such buildings in successful operation, and New York is also contemplating a similar project.

Bellevue Hospital Medical College and the Medical Department of the University of the City of New York will extend their medical course to four years. The change goes into effect at the beginning of the next session.

An epidemic of jaundice is prevailing in Albany, N. Y. This city has been repeatedly visited by epidemics, but in this instance no local cause has been discovered to account for the malady.

The death is announced of Dr. Richard M. Hodges, of Boston, late surgeon to the Massachusetts General Hospital and adjutant professor of surgery in Harvard University, where he was also associated with Dr. Oliver Wendell Holmes.

The medical profession of Cincinnati has suffered a great loss in the death of Dr. C. G. Comegys, which oc-

curred on the 10th instant. Dr. Comegys was an old and honored citizen, and during a long career had occupied many positions of trust with unvarying fidelity.

As was suggested in our last issue, a movement is on foot looking to the early presentation at Albany of a bill prepared for the purpose of restricting vivisection in public schools. While the avowed object is harmless when thus limited, modifications may readily be introduced during passage, and it is evident that the measure deserves close watching.

A surgical amphitheatre in connection with Charity Hospital in New Orleans has been recently completed and appropriately named in honor of the late Prof. Miles of that city.

THE last number of the *Boston Medical and Surgical Journal* notices an attempt by legislation to enforce the use of secret remedies upon the State hospitals. Such a step would certainly establish a precedent of the most dangerous type.

THE reports in January from St. Petersburg showed no evidence of abatement in the epidemic of typhus fever. Seventeen hundred cases already have been recorded.

THE *Journal of the American Medical Association* in its issue of the 15th presents illustrations and description of a new bone-cutting forceps, invented by Dr. Allen Devilbiss, of Toledo, Ohio. Its usefulness in cranial surgery is particularly apparent, and the ingenuity and simplicity of the instrument appeal strongly to the surgical mind.

THE membership of the British Medical Association has been increased recently by the admission of 227 new members.

A disastrous fire occurred in the laboratories of the Royal College of Physicians of Edinburgh on January 31 entailing great loss in apparatus and specimens. No amount of insurance can repair such damages.

THE government of India, besides recently establishing an Imperial Bacteriological Laboratory, has now taken a further step in the appointment of special sanitary officers, possessed of bacteriological knowledge, for each large cantonment. The information acquired in this manner cannot fail to place the sanitary laws of the Empire upon a more scientific footing as well as greatly increase the *data* available to the medical profession.

M. DAREMBERG, of Lyons, France, has found the exclusive use of phosphated milk of value in the preventive treatment of tuberculosis. He recommends the use of goat's milk as follows: "Phosphated milk can be obtained by making a goat absorb a daily dose of twenty grammes of powdered calcined bones mixed with ten grammes of sea salt and combined with bran, barley, or oatmeal and crushed carrots. In this way the phosphates are assimilated by the animal and supply the child with a reconstituent form of food."

SOME interesting points relating to the precision of information revealed by the microscope have been developed in a recent murder case before the authorities at Yonkers, N. Y. The details of the conflict indicated a hand-to-hand struggle. Three parties were arrested, the circumstances implicating two of them very positively. The coroner took parings from the finger-nails of all three and submitted them to a microscopist, who reported that he found blood on the nail parings of the third only. As the victim was an elderly woman, the next step in the argument is to discover the age of the person to whom the blood belonged.

THE crew of the American ship *El Capitan*, which has just arrived in New York harbor from Japan, have been victims on the voyage of what is known in seafaring vernacular as "moonblink." The captain reports that the men slept on deck in the moonlight for nine nights while passing through the China Sea. At first they suffered from night-blindness, and later they could not see at all on account of suppuration and ulcers of the lids. The constant bathing with salt water and the improved air after rounding the Cape of Good Hope helped to restore a healthier condition, but some of the men are still suffering, and one will probably lose his sight entirely.

CORRESPONDENCE.

To the Editor of THE MEDICAL NEWS.

SIR: I have just finished reading, with pleasure, your editorial on "Preference of the Diphtheria Bacillus for the Tonsil." I wish to suggest that you treat your cases of *nasal* diphtheria with the "dead air" method, by plugging the anterior nares with cotton, thus limiting the production of the baneful toxin in that inaccessible region, by shutting off the necessary *current* of air.

Very truly yours,

T. B. HILL, M.D.

THE RECENT EPIDEMIC OF DIPHTHERIA IN CHICAGO. RESULTS OF THE SERUM-ANTITOXIN TREATMENT.

[SPECIAL CORRESPONDENCE TO THE MEDICAL NEWS.]

DR. E. P. MURDOCK, Medical Inspector of this city, recently submitted a preliminary report of the work of the auxiliary medical corps of the City Health Department, the period of whose appointment terminated on the 21st of January. In his report Dr. Murdock says: "When, in the latter part of September, 1895, the daily reports of diphtheria gave indication that we were threatened with an epidemic of the gravest character in the history of the city, the assistant commissioner, Dr. F. W. Reilly requested me to give my attention to the situation and respond to the call of physicians for the administration of antitoxin, and such other duties as in my judgment would assist in staying the ravages of the disease. Accordingly I began my work by responding to the call of physicians for the administration of antitoxin, the verifying of diagnosis by bacterial examinations, and the relief of laryngeal stenosis by intubation. In connection with this work I also investigated the causes which led to rapid spread of the contagion, gave directions for isolation, made notes of

the environment, immunized children exposed, and co-operated with the attending physicians in all respects to restore patients suffering from diphtheria, and to protect the public from further exposure. Within twenty-five days I had treated ninety cases of diphtheria with only four deaths, immunized twenty-two children who had been exposed to diphtheria without a single case of contagion, and carefully noted the effect of treatment in all its phases, which led to the following conclusions, which were reported to the department:

1. "No evil or deleterious effects follow the administration of antitoxin which can be attributed to the use of the remedy either with diphtheria patients or with healthy children for protective purposes.

2. "No child treated for immunity has contracted the disease, no matter how much has been the exposure.

3. "All patients are benefited by the treatment when administered in time to accomplish any results with a reasonable hope of recovery.

4. "The administration of antitoxin does not in any way interfere with other treatment.

5. "Careful observations were made to determine the sources of infection and the agencies which led to the spread of contagion, and the following conclusions are submitted:

1. "Failure to isolate patients and prevent unlimited visiting and open communication with friendly neighbors, and even the public schools.

2. "Failure to destroy or properly disinfect clothing and other material which had been in contact with the patients, and the lack of proper fumigation and cleansing of premises.

3. "The public character of funerals to the extent of exposing the body of a child dead from diphtheria to public visitation of friends and neighbors, they not only viewing the body themselves but permitting their children to come in immediate contact and even kiss the dead child's face; nor was this all, but the bodies of children who had died from malignant diphtheria have been taken into churches for public services, and their little playmates have acted as pallbearers without the least effort to even cleanse or protect the mouth or nostrils of the corpse.

4. "The unsanitary condition of water-closets, especially in districts where old outside vaults are still in use without washouts or sewer connections.

5. "Failure to report the so-called 'mild cases' which were exposed to indiscriminate contact with their little friends, from which many a malignant case developed."

From these causes he had traced about eighty cases of diphtheria with twenty deaths, all of which might have been avoided by proper precautions. The character of the epidemic, the variety of sources for the spread of the contagion, and the increasing inquiries for the use of antitoxin caused the work to grow to such an extent, and the demand from members of the medical profession for further assistance became so great, and at the same time the increase in the spread of the disease became so marked, that Commissioner Kerr determined to apply for more assistance through the organization of an emergency staff, and in support of this request it was shown that from thirty-four to forty-three cases of diphtheria were being reported daily, with a rapidly increasing number of deaths, and the necessity was urged of an organized systematic effort to control the ravages of this disease which was destroying more lives in a single year than had been lost from smallpox in a decade. A special appropriation having been secured by the Commissioner for this emergency, the following well-known physicians were appointed and organized into an auxiliary medical corps of the Chicago Health Department, for the control of diphtheria: Dr. Samuel J. Walker, Dr. Wm. K. Jaques, Dr. G. C. Krieger, Dr. Martin J. Ritter, Dr. Rosa Englemann, Dr. H. H. Latimer, Dr. W. A. MacFarlane, Dr. R. W. Hardon, Dr. Hamilton H. Forline, Dr. J. A. Egan, Dr. Frank S. Churchill, Dr. J. W. Walker, Dr. J. J. Clausen, Dr. A. H. Roler, and Dr. J. C. Brydges. The city was divided into districts, with an inspector placed in charge of each district, three being detailed to supervise funerals and prevent so far as possible the spread of contagion from this source. Their service began November 22, 1895. The inspectors were instructed to ascertain the facts about all cases of diphtheria in their respective districts, and to use all means in their power consistent with professional ethics and under authority of law, to conserve the true interest of the public for the control of this disease. They were further instructed that there was no desire on the part of the department to supplant or in any way interfere with the prerogatives of the family physician, but on the contrary they were strictly enjoined to communicate with the physician in charge, and if possible to meet him and cooperate with him in the work in hand, so that all assistance which could be rendered to the family should be administered through the agency of its own physician, thus sustaining as far as possible the relations which should exist between a physician and his families. They were also instructed, wherever it was possible, to determine by bacterial examination the true character of the disease; to learn whether antitoxin had been used or not, and if so, on what day of the disease, and the results; and at all times, so far as it lay in their power, to subserve the interest of the family physician, while protecting the public health.

Incubators and culture boxes or tubes were furnished for bacterial examinations, and such other supplies as seemed absolutely necessary for the work. A system of rules was formulated for the isolation of patients and the care of sick rooms which would justify the removal of diphtheria display cards by the inspector, when, in his judgment, all sources of the spread of contagion were absolutely shut off, and a communication was addressed to the medical profession and the public, setting forth these points and asking their co-operation.

From the detailed reports of the members of the corps, submitted from time to time, the appended summary of the work performed has been compiled. Comment upon these figures is deferred until cases now under treatment are reported on. The summary embraces all cases disposed of up to and including January 10th.

For the present Dr. Murdock contents himself with saying that he is entirely satisfied with the result; that the members of the auxiliary corps have reason to be gratified

with the showing, and that the figures are commended to the attention of the medical profession as a contribution to the study of the antitoxin treatment and prevention of diphtheria comparing favorably with the best results obtained elsewhere.

SUMMARY OF WORK OF ANTITOXIN CORPS OF HEALTH DEPARTMENT, NOVEMBER 22, 1895, TO JANUARY 10, 1896.

Total number cases diphtheria visited,		1221
At request of attending physicians	1169	
Charity cases, (no physician in attendance	52	
		1221
Total number found convalescent on arrival,	63	
" " " dead " "	50	
All other cases,	1108	
		1108
Total number found suffering from diphtheria,		1108
" " treated with antitoxin,	1047	
" " in which antitoxin was not used.[1]	61	
		1108
Total number recovered under antitoxin treatment.	961	
" " died " " "	86	
		1047
Death rate under antitoxin treatment 8.93 per cent.		
Total number in which antitoxin was not used,[1]	61	
" " of those known to have died,[1]	32	
Death rate where antitoxin was not used 52.46 per cent.		
Total cases treated with antitoxin,		1047

Total number of children and others exposed to the disease and treated with the protective dose of antitoxin, 810

Total number of these who subsequently contracted diphtheria, 4

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 4, 1896.

EDWARD D. FISHER, M.D., PRESIDENT.

SCLERODERMA.

DR. LEONARD WEBER reported a case of scleroderma with the following history: Mrs. C., a farmer's wife, of German parentage, was first seen October 26, 1894. She was of medium height, quite stout, of pale and sallow complexion; hair of scanty growth. She was intelligent, and physically able. There was no hereditary or acquired taint. She had had five children and one miscarriage. During the thirteen years of married life she had had two severe uterine hemorrhages, one after a labor, and the other after a miscarriage. Three years ago she noticed that the right arm and side of the neck were becoming stiff and hard in patches. Gradually "strings" of cicatricial-like tissue developed beneath the cutis of the upper arm and wrist. There had been no contractures, and these strings had developed in the first year and a half of the affection. The sclerosis extended a little to the left of the median line. There was a small sclerotic patch on the chin and in the lower lip. The sense of touch, and the feeling of pain, and the muscular action were apparently normal. The surface temperature of the sclerosed area was about one degree lower than that on the other side. There was an effusion of fluid in the pre-patellar bursa associated with some tenderness. The right knee was also tender, but showed no effusion. She also complained of rheumatoid pains in the lower extremities and muscles, but not specially distributed along the nerve trunks. The tendon reflexes were normal. Her appetite was good, and for several months previously she had had a slight looseness of the bowel. The urine had a specific gravity of 1014, but contained no albumen or sugar. The treatment was directed first to improving the general condition—giving quinin, sodium salicylate, sodium bicarbonate, and small doses of morphia to check the diarrhea. After this she was given increasing doses of Fowler's solution, but there was no improvement in the scleroderma. On January 25, 1895, treatment was begun with the English thyroid tablets, giving five grains, three times a day. All other treatment was suspended except the use of elixir of calisaya. When seen on April 2d, after having taken 100 of the tablets, she was very much improved; the cicatricial strings and the patches on the lip and chin had almost entirely disappeared. When seen again, October 3, 1895, she had taken 280 tablets, stopping for two weeks after each 100 tablets. The improvement had been steady and marked. The speaker said he was disappointed that the patient had not come this evening, as had been expected she would do. Neurologists were inclined to look upon scleroderma as a disease of trophoneurotic origin, and he had nothing new to add regarding the etiology or pathology of the disease. All that he wished to say was that when last seen this woman was *practically* cured.

DR. B. SACHS said that he was reminded of a patient who had come under his notice about three years ago—a widow of about 45 years. She had had extensive sclerodermatous patches for a number of years previously. When first seen by him, a course of massage and galvanic treatment had been adopted, but only very trivial improvement had been observed. She was very slow in all her movements, and was unable even to pout her lips. Her face presented the appearance of one with double facial hemiatrophy. She also had very abundant deposits of yellow pigment in the hands, particularly in the spaces

[1] "Not used," either because the patients were dying when first seen, or because the families or attending physicians changed their minds after calling in the department physician and refused the antitoxin treatment.

between the knuckles. In January, 1895, she was placed on the thyroid treatment, receiving two to five grains of the pulverized extract of thyroid, three times a day. She did not return, as directed, after a week, but instead remained away for three weeks. At this time she was so greatly emaciated that he had since been led to employ the thyroid as an anti-fat remedy before he had read anything about it in the German journals. But aside from this emaciation, the scleroderma had undergone a most remarkable change for the better, and the spots of pigment had disappeared. When seen last, some months ago, she was apparently cured. The question of whether or not the scleroderma was a thyroid disease, he was not at present willing to discuss. He was fully convinced that the scleroderma was not *cured* by the thyroid; it had been necessary to keep his patient on about two grains a day of the thyroid.

DR. PEARCE BAILEY referred to a case of typical scleroderma which had lasted for five or six years, and had resulted in immobilization of the elbow and the knee. He had given her Parke, Davis & Co.'s thyroid extract, five grains, three times a day, for a month or two, but without any appreciable improvement.

DR. WILLIAM H. THOMSON said that he would certainly recommend the trial of a thyroid extract made by another firm, because he had known a case to undergo relapse after changing from the thyroid extract of another manufacturer to that of the firm referred to by the last speaker.

DR. WEBER, in closing the discussion, said that there had been very little loss in weight in his patient during the thyroid treatment—about fifteen pounds after having taken the first 100 tablets. When last seen he had not noticed any great loss of flesh. The disease was very chronic, and he feared there would be a relapse.

SYMPATHETIC NERVE SYMPTOMS WITH ULNAR PARALYSIS FOLLOWING DIPHTHERIA.

DR. B. SACHS presented a girl of 14 years, who still exhibited the remnants of a poliomyelitis of the right upper extremity, which came on when she was about 18 months old. It would be noticed, he said, that the atrophy of the arm was extreme. In March, 1895, this girl had had diphtheria, and after this had developed an atrophic paralysis of the left upper extremity, chiefly of the muscles of the hand, and more particularly the interossei muscles. This condition was associated with a narrowing of the palpebral fissure on the left side, and it was for this reason that he presented the case. There could be no doubt that ever since the beginning of the poliomyelitis the left side had been entirely normal up to the attack of diphtheria. Examination had shown that there was a diminution of all the forms of sensation in the ulnar distribution on the left side. The condition of the hand might be possibly due to a poliomyelitis, but owing to the presence of sensory disturbances and the very acute onset of the trouble after a diphtheria, this could be safely excluded. The diagnosis, therefore, was a peripheral neuritis coming on after diphtheria. The curious point was the association of the sympathetic nerve symptom with this peripheral neuritis. The only way he could account for it was by supposing that the affection must have been very near the issuance of the roots of the spinal cord, and in that part where there were communicating branches between the roots and the sympathetic nervous system.

DR. C. A. HERTER said he was not sure that the possibility of the cord being involved at the level of the ilio-spinal centre could be excluded. The narrowing of the lid and the contraction of the lid on that side would suggest very strongly that the cord was involved, or the roots were involved close to the cord. He had never seen that symptom in a peripheral lesion, which without any doubt could be said to be strictly limited to the peripheral nerves. He had seen this ocular symptom several times in cases of crushing injury to the spinal cord.

DR. WILLIAM H. THOMSON said he agreed with the last speaker that the case appeared to be one of localized myelitis. Such cases were not unknown in connection with pheripheral palsy. It would be very difficult to account for that association on any theory of peripheral neuritis. For a good while he had given up the idea that a diphtheritic paralysis was necessarily a neuritis; he thought the changes were very often characteristic of pure degenerative processes rather than inflammatory processes. More than once had he met with cases which could be explained better on such a theory.

DR. SACHS said that the case was an unusual one, and had been very closely studied by him for a number of months. He had at first supposed there was a myelitis or a poliomyelitis on the left side, but he had abandoned that idea because of one symptom which would be hard to explain if there were only a myelitis, *i.e.*, the sensory disturbances in the arm. He saw no reason to depart from the diagnosis he had expressed. He believed that this case differed from others of diphtheritic palsy in that instead of the pheripheral portion of the nerve being affected by the diphtheritic poison, the part of the plexus very near to the spinal cord was affected—in other words, the nerve roots. Between the anterior roots and the sympathetic system were communicating branches, and if one or more of these branches were affected, the influence of the ilio-spinal centre would be cut off. This would explain the loss of function without supposing an invasion of the cord.

DISCUSSION ON THE DIFFERENTIATION OF SKIN AND MUSCLE SENSATIONS AS A MEANS OF DIAGNOSIS.

DR. C. A. HERTER said that he believed dissociation of sensation was met with, especially the loss of pain and the temperature sense, with only a partial loss of the tactile sense, in cases of peripheral neuritis. He had seen cases of alcoholic neuritis in which in certain areas of lost sensibility this condition was present, and this was particularly true late in the disease when the period of hyperesthesia had passed. But he had not met with any cases of absolute loss of pain and temperature sense with preservation of the tactile sense except those which might be reasonably supposed to be instances in which the lesion could be located in the spinal cord. He called attention especially to cases of hemorrhage into the spinal cord, and particularly into the central canal. About a year ago

he had had a patient in the City Hospital who had fallen into a hatchway and struck on the right shoulder. This man said that immediately after this accident he had been partially paralysed in all four extremities. When seen by the the speaker, about two months later, there was an atypical Brown-Séquard paralysis. His right leg was completely paralyzed; the left leg exhibited loss of sensation to pain and temperature with perfect preservation of tactile sense. The internes of the hospital had made a diagnosis of syringomyelia, as had been expected. After two or three months, there had been a gradual return of pain and temperature sense. This case was undoubtedly one of hemorrhage into the gray substance of the cord. He had noted in the recent literature reports of half a dozen cases of a similar character. From this it appeared to be an established fact that hemorrhage into the central canal and gray matter of the spinal cord was very apt to give rise to this symptom. These were the only conditions under which he had met with this particular dissociation of sensations.

DR. SACHS said that it had probably been the common experience with most neurologists that whenever the pain and temperature sense were diminished or lost, and the tactile sense remained, the case was looked upon as a gliosis or a syringomyelia, particularly if associated with atrophic palsies in the parts where the sensory disturbances were manifest, and the reflexes altered in the lower extremities, showing on the whole a process most marked in the cervical portion of the cord. His experience had led him to doubt the pathognomonic value of this special symptom. Many years ago Weir Mitchell had described this dissociation of sensation in injuries of the peripheral nerves without attaching much importance to the symptom. The cases in which the speaker had observed it, were several of syringomyelia and one case of Pott's paralysis. It was the occurrence in this last disease that had led him to give this subject considerable thought. This patient, an adult, was still under treatment for the disease, which had been progressive. When first seen by the speaker, the man had been supposed to be suffering from vague rheumatic pains, but an incipient kyphosis had been found, and other symptoms indicating Pott's disease and Pott's paralysis. On making the sensory examination, he had been greatly surprised to find a very distinct dissociation of sensation in exactly the order observed in cases of syringomyelia. He had therefore been inclined to think at first that there must be some central changes in the cord in this case, but further progress of the case had shown it to be simply one of Pott's paralysis and nothing else. At the present time this man had spastic rigidity of the lower extremities without any involvement of the bladder, or other symptoms pointing to marked myelitic changes. Moreover there was now complete loss of every form of sensation. He was inclined to regard the condition therefore as having been due to the first impact of the vertebral trouble—that in this case it was practically a root trouble. We were likely to get this dissocation in all these diseases beginning, not in, but around the spinal cord, choking up some of the root fibres.

Six years ago he had seen a case presenting distinct atrophic paralysis in both upper extremities, with slight increase in the reflex in one lower extremity, and with a distinct dissociation of sensations, as seen in syringomyelia. The man gave a specific history. The progress of this case had shown that in all probability it was one of localized specific meningitis around the cervical portion of the cord. The disease had become absolutely stationary; he had developed no other symptoms, and yet there was loss of tactile sense and absolute loss of the muscular sense, with preservation of the pain sense. The temperature sense was diminished. Such a case showed that we must not attach too much importance to that special form of dissociation of sensations which had been associated with syringomelia. He had still another case under observation—one of gliosis, in which there was some dissociation of sensation, but not exactly of the kind ordinarily described as present in such cases. This symptom of dissociation, he thought, would occur where the central gray matter was affected, whether from hemorrhage or central gliosis. The greatest importance should be attached to the fact that it was a symptom of

DR. N. E. BRILL said that about ten years ago he had reported a case which would corroborate the position taken by Dr. Sachs. It was one of fracture of the lamina of the fifth cervical vertebra. The patient was then 30 years of age, and the fracture had occurred when he was about ten years of age. When seen by the speaker he had presented marked signs of compression of the cord with some anomalous muscular dystrophies. Dr. Sayre had examined the case and found undoubted callus, and on pressure posteriorly, over the injured region, there had been a sensation of cold, which the patient had himself noticed previously.

DR. HERTER said that while he would agree with Dr. Sachs that damage to the posterior nerve-roots might be a cause of dissociation of sensations, his experience had been that it was ordinarily not so. In most cases in which the vertebræ were so fractured as to give rise to compression of the nerve-roots, and in most cases of tumor in which the posterior nerve-roots were implicated, all forms of sensibility were abolished at the same time. He had seen several cases of fracture of the vertebræ with pinching of the nerve-roots. In some of these the autopsies had shown that only the nerve-roots had been damaged. In these cases all three forms of sensibility had been lost.

DR. SACHS said that he did not wish to be understood as considering disease of the nerve-roots a frequent cause; he only wished to point out the possibility of such a cause.

DR. IRA VAN GIESON said that there was much reason to believe that the long fibres in the posterior columns conveyed pressure or tactile sensations. There was probably a small complement of fibres which also conveyed muscular-sense impulses. It seemed to him to be pretty definitely shown that the column of Gowers conveyed pain sensations. There were some cases which seemed to show that temperature sensation and pain sensation traveled together. The tract of Flechsig seemed to be

concerned with a conveyance of muscular impulse. In syringomyelia, the pain tract was liable to be interrupted; but whether this column of Gowers was interrupted, or the interruptions occurred in the cord, there was invariably an analgesia of the opposite side. When these tracts in the medulla were separated, so that tumors might destroy one or the other of them, it was found that Gowers's tract, in certain cases, conveyed temperature and pain sensation; Flechsig's column, muscular-sense impressions; and the posterior columns, tactile sensation and muscular sense. Regarding the association of muscular and painful sensations clinical evidence was conflicting. In some cases there might be a distinct loss of pain sensation, but not of temperature sensation. One might conclude, therefore, that in certain individuals the temperature-sense fibres passed along with the pain fibres, and that in other cases they pursued another course. He thought that certain reported cases of syringomyelia of traumatic origin had been nothing more or less than hemorrhages into the spinal cord. Hemorrhage into the spinal cord was liable to assume a columnar distribution in the lymphathics or perivascular spaces which pass in from the anterior spinal artery. In his opinion, a lesion of the posterior roots would result, not in dissociation of sensory impressions, but in destruction of several of them at the same time.

The recovery of lost functions, as shown in Dr. Sachs's case, was an exceedingly interesting topic. The only explanation seemed to be the cutting off of the conducting path at some particular level, and the seeking out of new channels of conduction in the spinal cord.

DR. A. WIENER said that he had also observed Dr. Sachs's case of Pott's disease, and had since then examined other cases regarding the dissociation of sensations. He had been surprised to see how often this occurred. He had, however, never yet found in any particular case such a complete absence of pain and temperature sense as in syringomyelia. If the temperature and pain senses were simply diminished, the lesion might be at the roots or at the cord, but where they were completely absent we could be pretty sure about placing the lesion within the gray matter of the spinal cord.

DR. SACHS said that Dr. Van Giesen expected all forms of sensation to be abolished when there was a lesion affecting the posterior roots. In reply, he would say that a case had been reported some years ago by Thompson, in which there was clinically a distinct nuclear palsy, yet at autopsy there was found to be an infiltration of the third-nerve root-fibres, and this infiltration had evidently choked up some of the fibres, but not all of them. In the case of specific disease, it had been shown that a lesion might affect part of the root without involving all the fibres; hence, he felt that dissociation might after all be due to partial affection of the posterior root-fibres.

DR. ONUF said that if we assumed an affection outside of the spinal cord we must assume that it is at the point of union of the two roots, where the sensory fibres had passed the spinal ganglion and joined the motor roots. It was at this point that the communicant branch of the sympathetic nreve, which conducts the pupillary fibres, entered. Such a combination of symptoms could not be explained by any other lesion. Dr. Sachs's patient showed impairment of tactile sensation for the sense of pressure and that of pain. It was hardly possible to assume that such a combination of symptoms could be produced by an affection of the gray substance of the cord; we must assume an affection of the eighth cervical and first dorsal nerve close to the point where the motor and sensory roots meet the communicant branch which conveys the fibres to the pupil.

DR. HERTER said that we must distinguish quite sharply between the cases in which pain and temperature sense were absolutely lost and the tactile sense perfectly preserved, and those cases in which the tactile sense was nearly perfect, and also between cases in which tactile sense was perfect, but there was a partial loss only of the pain and temperature sense.

DR. VAN GIESON said that the example quoted by Dr. Sachs was hardly a parallel, for in that case the anterior roots were involved. The fibres of the posterior roots all had different functions, while the anterior root was strictly motor. He was willing to admit that there might be chronic processes which would only involve certain fibres of a root.

DR. CHARLES L. DANA said that: (1) Differentiations of cutaneous sensations did not occur in peripheral neuritis except to a very minor extent. The only exception which he recalled was the doubtful one of Norvan's disease, and perhaps of leprous neuritis. (2) Differentiations of cutaneous sensations occurred in spinal-cord diseases, but only completely in those diseases involving the central part of the cord (traumatic hematomyelia, syringomyelia). In columnar and spinal-root disease, like tabes, the differentiations occurred, but were never complete—*e.g.*, complete separation of touch from pain or temperature anesthesia—at least this has been his personal experience. (3) Differentiations of cutaneous sensations occurred most strikingly and completely in ponto-bulbar lesions, and were of diagnostic value here, taken with other symptoms. (4) Differentiations of cutaneous sensations did not occur in any sharp extent in organic cortical lesions. The cutaneous "locality-sense" was the one most singled out. (5) Differentiations of cutaneous sensation did not occur completely in hysterical anesthesia, though the pain sense was most involved. There were some exceptional cases in which the pain sense was distinctly singled out. The differentiation of cutaneous sensations, therefore, was least in peripheral-nerve lesions, increased in spinal-root lesions, and again in central spinal-cord lesions. It was most striking and complete in ponte-bulbar lesions, and became very slight again in cortical lesions. Through the whole series the pain sense was the one oftenest differentiated, except in cortex cerebri.

THE PRESIDENT said that in cases of transverse myelitis, although there was a loss of sensation, the pressure sense might remain. It was possible to imagine a lesion from hemorrhage into the cord, which would follow out exactly the lines of syringomyelia. It must be, however, a very rare condition.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Regular Meeting at the Philadelphia College of Physicians, February 12, 1890.

Dr. J. C. Wilson in the Chair.

After reading of the minutes, the Chair announced that the President's annual address would be deferred in order to give the entire time to the guest of the evening. He then introduced Dr. Simon Baruch, of New York, who had been invited to address the Society on *The Importance of Precision in the Technique of Hydrotherapy*. Dr. Baruch said that this invitation was a gratifying evidence of the awakening of the profession to the merits of hydrotherapy. He gave as his reasons for warmly advocating water, that he had obtained a large and favorable experience with it, and had found the average practitioner as poorly informed upon it as he once was. Dr. Baruch referred to having made the first plea for the Brand bath in typhoid, in 1889, which was not favorably received. The fact that by persistent agitation it has come about that the method is now practiced and taught in many hospitals and colleges, has encouraged him to continue his propaganda. Water is the most flexible remedy we possess, because we may vary its effects by a judicious use of temperature, pressure, duration, and technique. Dr. Baruch then discussed the reasons for the apathy of the profession on this subject. He regarded the principal cause to be an inexact technique, each man modifying it to suit his own ideas. He then illustrated his subject by giving the rationale of the Brand bath and its application in fulfilling the chief indications in typhoid fever, which arose from the overwhelming of the nervous system by the toxemia. He described how a strict Brand bath of 65° for fifteen minutes, with constant friction, repeated every three hours, when patient's temperature is 102.5 or over, arouses the nerve centers step by step, overcoming the toxemia. He insisted that the Brand method, which is definite in its technique, must not be charged with failures attending its modifications, any more than Bergman's aseptic surgical technique should be charged with failures attending the neglect of any one of its exacting demands. Dr. Baruch referred to the diagnostic value of early bathing. He begins with a bath of 90°, follows with 80°, and then 75° every three hours. If the rectal temperature is reduced two degrees or more typhoid fever is excluded; the smaller the reduction of rectal temperature, the more positive is the diagnosis of typhoid fever.

In the treatment of pneumonia, Dr. Baruch has devised a method whose success warranted him in commending it to his colleagues. He administers 15 to 20 grains calomel, and then envelops the chest with a thick linen compress, slit in the axillæ, to fit it high up, soaked in water at 60° F., and covered by a flannel bandage an inch wider and larger. This is renewed every hour if temperature is 100° to 102°, every half-hour if higher. No medicines or stimulants are given, except, in alcoholics; hypodermics of strychnine for heart failure. The results have been very favorable in his private practice and that of Dr. Harry Pemberton, of Long Branch. In the Manhattan Hospital, the general mortality of pneumonia has been reduced one-half, while in cases coming under treatment before the fifth day the mortality is as 12 per cent. to 17 per cent.; all the cases having been treated by Drs. Daniels, Knickerbocker, and himself, and reported by Dr. A. J. Wittson. Dr. Baruch explained the *rationale* as resting upon the repeated gentle shock and stimulus to the periphery conveyed to the nerve centres, deepening the inspiration and removing obstructions in the bronchi; invigorating the heart by widening the area of the cutaneous vessels. These cases rarely resolve by crisis. While the symptoms subside very soon, they seem to recover slowly but surely.

That precision in the technique is as important in chronic diseases as in the acute may be readily demonstrated. So little is this understood that a certain hydrotherapeutic establishment announces an easy way to prescribe water by presenting the following, to be sent by the physician: "Give bearer a douche, pack, barège bath—the physician may strike out the bath not wanted." One may as well order a patient to obtain quinine, strychnine, or morphia without stating dose, method, and time of administration, etc. A prescription for a "bath" should state temperature, duration, and pressure as well as kind of "bath" wanted. The terms cold, hot, tepid bath should be abolished, and definite temperatures prescribed instead. A cold bath in New York city would be 40° in midwinter, 80° in midsummer.

Dr. Baruch cited phthisis as a disease remarkably amenable to hydriatic treatment, given with judgment and precision; as demonstrated in the Montifiore Home, where a patient may be seen now who has gained thirty-three pounds. A gradual, slow accustoming of the patient to low temperature and high pressure is advisable in order to elevate the patient's nutrition and hematosis.

In neurasthenics, Dr. Baruch finds it important to vary the technique, temperature, and pressure with the type and condition of the patient. A cold douche which would set an erethetic neurasthenic wild would act favorably upon one of the depressed type.

Dr. Baruch cited from the lectures of two eminent neurologists directions for using "the cold-water treatment," in order to warn against their indefiniteness and recklessness, and against the error of regarding the most agreeable bath as the most useful.

He detailed his method in chlorosis to be the standing in water at 100°, and gentle but rapid ablutions of the patient in water at 90°, reduced daily one degree until 60° are reached, followed by drying and friction.

In conclusion, he objected to hydrotherapy being charged with the failures due to an inexact technique and lack of judgment in its application.

Discussion.

Dr. Tyson expressed himself as entirely in accord with the reader's views regarding the life-saving value of the Brand bath in typhoid. He was free to acknowledge that he had not followed the strict technique of Brand, inasmuch as he was under the impression that Brand bathed whenever the temperature reached 102° F. He

had, therefore, in hospital practice bathed his patients every two hours, instead of every three, without harm. Dr. Baruch had informed him, in response to an inquiry if his method was correct, that the objection to these faequent baths was the discomfort produced by them, and that he [Dr. Baruch] preferred to follow strictly the three-hours method, because it had given the best results. Dr. Tyson would therefore in future adopt the strict technique of Brand, which is a great improvement on all other treatments of typhoid. He had found the Burr rubber bath, given in bed, a good substitute for the tub.

DR. HOBART A. HARE said he believed in an exact technique, and commended the reader for insisting upon it. He did not regard the Brand bath as a heat reducing bath, but as a stimulant to the nervous system, as held by the reader. He was not sure but that the fever was salutary in most cases and should not be suppressed too violently. In pneumonia we have increased leucocytosis even if we have a high temperature, and may be the case within the body in typhoid. At all events the use of the coal-tar antipyretics is indefensible, because it has been proved that they diminish oxidation. Cold baths increase metabolism. It has been shown by Liebermeister, Roehirg, and others that the internal temperature rises after cold baths.

DR. TURCK, of Chicago, expressed surprise that the Brand method should require discussion or defense in Philadelphia, where J. C. Wilson has so triumphantly indicated it years ago. He regarded Dr. Baruch's insistance upon making the technique of hydrotherapy exact, as of great importance. Dr. Turck had devised a method of relieving internal congestion by placing the patient into a tub of water at 98°, and gradually raising the temperature until 120° were reached. When the skin was intensely red and the surface vessels well filled, he takes the patient out and rubs him with blocks of ice, dries him, and puts him to bed. He has found this method useful in any disease manifesting internal hyperemia, and has demonstrated its *rationale* in animals by vivisection.

DR. CROZIER GRIFFITH does not regard the cold bath as useful in the broncho-pneumonia of children. He prefers very hot baths and finds these stimulating and effective.

DR. ANDERS said that he values the cold baths in typhoid, but they were objectionable in many respects, and he regretted that there were no substitutes. He had often favored the addition of alcohol to calm the fears of patients and friends, and secure consent to cold baths, if so treated. The Burr bath he regarded as very useful, because it enabled one to lower the temperature gradually and not shock the patient too much. A feeble heart was his greatest contra-indication to the cold bath.

DR. WHARTON SINKLER said that in neurasthenia we have no more valuable remedy than cold water judiciously used. He referred to the dripping sheet as exceedingly valuable for insommia. He had seen a hot bath reduce temperature two degrees.

DR. T. J. MAYS spoke in warm commendation of the ice treatment in pneumonia, and said that the application of ice-bags over the seat of the involved area hastened resolution, removed exudates and acted favorably upon all the symptoms.

DR. BARUCH in closing the discussion thanked the Society for their generous and lenient criticisms. He felt gratified by the cordial reception of the principles he advocated. The reason why the advocates of the bath treatment resent the prominence given to high temperature is that the proper understanding and adoption of the baths have suffered from this bugaboo, viz.: that cold water has always been regarded as an antipyretic. This was illustrated forcibly by a conversation he had with an eminent Berlin professor in 1890, in the wards of the Urban Hospital. His expectation of meeting a warm advocate of the Brand method was rudely shaken when the professor said, "Weg mit der Antipyrese." Because antipyrine was an antipyretic and had proved injurious, and because he classed cold water as an antipyretic, he condemned both with the same anathema. The cold bath reduces temperature but little; its good effect is entirely upon the nervous system. The increase of temperature after cold baths found by Liebermeister is true, but in these experiments very low temperatures were used, far lower than 65° (and in health). Indeed, Liebermeister himself, when teaching in Basle in 1867, applied cold baths in typhoid for temperature reduction, whose continuance he endeavored to maintain by large doses of quinine during the night. But while this was more successful than the medicinal antipyresis by salicylic acid and quinine then in vogue, Liebermeister abandoned his own method for that of Brand, as did most German clinicians. This illustrates clearly, Dr. Baruch said, the importance of always stating temperatures. While a fifteen-minutes bath of 65° F. reduces temperature somewhat, a shorter bath of 55 or less increases it by enhancing oxidation. Dr. Baruch did not share the surprise expressed by Dr. Turck, for he found much room for missionary work to convince the profession that the Brand baths were the best treatment for typhoid fever. When suggesting the cold baths in consultation he is not infrequently met by objection on account of patient's feeble pulse, just as has been objected here to-night. Dr. Baruch desired to emphasize the fact that cold water judiciously applied is the most potent heart tonic we have. There is no better example of asthenia with temporary heart failure than the fainting spell of a woman. The pulse is feeble or absent, respiration shallow, sensation and motion are practically abolished. Do we not dash cold water upon the patient, with the result of stimulating the nerve centres, to which the lungs at once respond by a gasp? the heart's response is shown by returning color to the pallid cheek. Here is a temporary cardiac failure; in typhoid it is prolonged, and due to toxemia. Dr. Baruch presented the following chart giving the summary of a case of typhoid now under his care, showing that without stimulants, heart beating 130 to 140, with a temperature of 104 to 105.6, was kept in good condition, being reduced to 116 to 120 by baths of 76° for twenty minutes with friction. He regarded the report as the best reply to the objections that cold baths are contra-indicated in heart feebleness. This patient

became cyanotic whenever the bath temperature was below 76° F., and yet she had practically no stimulants.

poisoning by arsenic, one does not want long descriptions of cases; a few typical cases will anwser; but if the entire

DR. BARUCH desired it to be understood that there are substitutes for the Brand bath. The sheet-bath, for instance, in which successive parts are douched and rubbed until they cease to warm up, is a good substitute. It is only necessary to understand the principles of hydrotherapy and the therapeutic indications of a case to devise a bath that will prove efficient. Dr. Baruch was glad to accept the clinical testimony of Dr. Mays in favor of the ice treatment of pneumonia. But he could not understand how the local external application of ice could exercise so direct an effect upon the subjacent inflamed lung, since he had been told by Dr. H. C. Coe that he had often seen the abdomen almost frozen by cold without producing any effect upon the subjacent peritonitis. The cold-compress method advocated by him seemed more rational and less disturbing to the patient.

REVIEWS.

A SYSTEM OF LEGAL MEDICINE. By ALLEN MCLANE HAMILTON, M.D., and LAWRENCE GODKIN, Esq., assisted by EMINENT COLLABORATORS. In two volumes. Vol. II, 680 pages and index. New York: E. B. Treat & Co.

THE general features of this publication were noticed in the review of the first volume. In this volume a considerable number of topics are discussed. W. R. Hornblower contributes a few pages on the duties and responsibilities of medical experts. The articles, being written by specialists in the respective departments, are, of course, trustworthy and representative of the existing state of the sciences, but there is a general tendency to diffuseness and a want of systematic arrangement in the order in which the articles are printed that leave an unsatisfactory impression on the reader. There is too much detailed case-reporting. In a work of this character the collection of cases from which judgment is to be drawn cannot be too large, but the *data* must be studied out and condensed by the writer of the article, so that those who consult the book may be able to determine easily the inferences to be drawn. Thus, in discussing list of reported cases could be tabulated so as to show the most frequent time of origin of symptoms, and duration, etc., the table would be of great value. We do not think it in good taste that extensive extracts should be made from von Krafft-Ebing's book.

The volume is freely illustrated.

PREGNANCY, LABOR, AND THE PUERPERAL STATE. By EGBERT H. GRANDIN, M.D., Consulting Obstetric Surgeon of the New York Maternity Hospital; and GEORGE W. JARMAN, M.D., Obstetric Surgeon to the New York Maternity Hospital. Illustrated with forty-one photographic plates. Philadelphia: The F. A. Davis Company, Publishers, 1895. Pp. 261.

A COMPANION volume to Obstetric Surgery, by the same authors, this book partakes of the same nature as far as its makeup is concerned. The photographic plates on the whole are excellent, but there are a few that are altogether unnecessary, inasmuch as they fail to impart any knowledge. The book is essentially clinical in its teaching, and in this respect is vastly superior to the Obstetric Surgery, which was largely composed from studies upon the manikin.

It is also eminently practical, the vast amount of theoretic and statistical information being made subordinate to the *facts* as encountered in the management of an ordinary gestation, labor, and puerperism. Only when absolutely necessary are the anatomic, embryologic and pathologic data inserted, and in this respect the book may rightly be regarded as unique. Drs. Grandin and Jarman have undoubtedly presented a useful volume, which will be especially serviceable to students and the more recent graduates in medicine. Unusual care seems to have been expended in the presentation of the mechanism of labor, which, unfortunately, is not as generally understood as it should be for the proper management not only of the abnormal but of the normal labor as well. The care of the infant is also ably discussed, and to a larger extent than is usual in works of this description.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, FEBRUARY 29, 1896. No. 9.

ORIGINAL ARTICLES.

THE ULTIMATE RESULTS, IN MY OWN EXPERIENCE, OF VAGINAL HYSTERECTOMY FOR CANCER ORIGINATING IN THE CERVIX UTERI.[1]

BY J. E. JANVRIN, M.D.,
OF NEW YORK;
GYNECOLOGIST TO THE NEW YORK SKIN AND CANCER HOSPITAL.

AT a recent meeting of the New York Obstetrical Society the question was raised as to the ultimate good resulting from the complete removal by vaginal hysterectomy of the uterus and appendages in cases in which the cancerous condition had begun in or had involved the cervix uteri; and the statement was made that the results were such as to raise the question as to the propriety of the operation in such cases. I took occasion to say at that meeting that my own results had been such as not only to encourage me, but to fully convince me that the operation was not only justifiable, but absolutely demanded; and I stated (from memory only) that my success had been somewhat over 50 per cent. In the very short paper which is given this evening I wish to give the statistics of my own cases in this *one* class, and to emphasize some points in the technique of the operation which may have had something to do with its success.

I find that during the past twelve years, among my cases of vaginal hysterectomy performed for various conditions, and nearly all of them for malignant disease, I have had sixteen (which constitute about one-fourth of the total number) in which the disease *primarily* involved the cervix.

These cases, for purposes of convenience, have been differentiated as follows: Five in which the cervix alone was involved, four in which the cervix and the upper part of the vagina were involved, and seven in which the cervix and the uterine body were implicated. Of the sixteen cases, twelve were operated upon prior to November, 1892 (Case No. 1 on May 17, 1884, and Case No. 12 on October 21, 1892). From this it will be seen that these twelve cases all date back three and one-fourth years or more. Out of these twelve cases three died within four days succeeding the operation (one from shock and two from septicemia). Of the remaining nine, recurrences of the disease took place in two instances, one dying about one year and four months, and the other about eighteen months, after the operation. Three others were lost sight of after six months or a year, but up to that time had not suffered from relapse. The remaining four, which complete the twelve cases operated upon prior to November, 1892, were all seen and examined at least three and a quarter years subsequent to the operation (some of them at a much later period), and in every case there was absolute exemption from redevelopment. Thus we have $33\frac{1}{3}$ per cent. cures in these twelve cases. In addition to the twelve cases mentioned I can add four of more recent date, as follows: One which occurred twenty-two months since, two last September, and one last October. Of these four cases, three are perfectly well, but in the fourth case (which is one of the two September cases) an unfavorable result was predicted during the operation, and at the present time there are evidences of return in the cicatrices in the vault of the vagina. Of course these four cases are of too recent date to base any statistics upon as to the ultimate result.

The youngest case among the sixteen was 34 years of age, and the oldest 72 years. Two were single, fourteen married or had been married, and nearly all of these fourteen had borne children. The three deaths occurred among my *earlier* cases, and were due to faulty or prolonged manipulations during the operation. If they had been operated upon during the past five years the death-rate would have been decidedly smaller, since I have had no deaths from this operation during that time. A few words as to the *technique* of the operation. I have stated that four of the sixteen cases had involved a certain portion of the vaginal mucous membrane as well as the cervix, and it is especially to these cases and the method used for the thorough removal of the diseased condition, together with a certain amount of healthy adjacent tissue, that these remarks apply. In a paper bearing the title "The Limitations for Vaginal Hysterectomy in Malignant Diseases of the Uterus," which I read at the

[1] A portion of An Inaugural Address of the President of the New York County Medical Association, delivered on February 17, 1896.

eighth annual meeting of the Fifth District Branch of the New York Medical Association, in Brooklyn, May 24, 1892, and which was published in the New York *Medical Record*, July 9, 1892, I spoke of certain cases in which the disease had extended from the cervix downward upon the mucous covering of the vagina, and I quote from that paper the following: "This condition is generally brought about simply by attrition. The epitheliomatous disease of the cervix coming in direct contact with the mucous surface of the upper part of the vagina simply irritates at first, but gradually, as the membrane becomes denuded, the poison becomes absorbed by it, and a focus for extension is added to the case. Fortunately for quite a time, in most cases, the conservative resources of nature are called into play, and a deposit of healthy, newly formed connective-tissue proliferation takes place in the vaginal wall, thus separating it from glandular and cellular structures beyond. In such cases an examination will show an extension of the disease to the mucous surfaces simply, the vaginal wall slightly, if at all, thickened, and no cancerous infiltration whatever under the wall, the vagina in all respects, excepting as to its mucous membrane, being practically normal. This condition does not in any way contra-indicate the operation. It simply complicates it by necessitating the removal of that portion of the vaginal wall upon which the disease has started, together with a half-inch or more of the healthy tissue below. This is best done by making the circular incision through the vaginal wall at a proper point at the beginning of the operation, dissecting upward and ligating any vessels which may cause sufficient bleeding to require it, and then as you reach the outer border of the cervix go on in the usual manner and extirpate the uterus." At that date I had had two such cases—one of three *years*' and one of three *months*' standing. Very shortly after reading the foregoing extract I had another. These three cases now date back as follows: No. 1, nearly seven years; No. 2, four years; and No. 3, three years and four months. These patients are perfectly well at the present time. No. 4 was operated upon in September last, and, as previously stated in the early part of this paper, an unfavorable prognosis was given at the time of the operation, from the fact that during the operation it became evident that the disease, although not infiltrated beyond the vaginal mucous membrane, had developed so deeply into the right broad ligament as to probably render *total* extirpation of all its *foci* an impossibility.

In operating upon these cases in which the vaginal mucous membrane had become involved I found it best in two instances to do a preliminary curettage, cleaning away all necrotic or loose tissue with the sharp curette, and then treating the case locally by the application of dry iodoform gauze every second day for a week or ten days, thus rendering the parts as aseptic as possible before extirpation was done.

I would like to add a few words as to another point bearing upon the thoroughness of the operation itself, and that is considering the amount of the broad ligaments which can be removed by the vaginal route. There are a certain number of cases in which there exists a thickening of the broad ligaments frequently associated with contraction in one or both, and resulting in more or less fixation of the uterus. Of course such a condition, if malignant, may occur in *any* case of malignant disease of the uterus, but much more frequently, I believe, in cases in which the carcinoma has extended to the uterine body, or has had its origin there, than in cases in which the cervix, or the cervix and the vaginal mucous membrane, have furnished the starting-point. In such cases the point to decide, if possible, is this: Is it the result of an old inflammatory trouble or a true infiltration of cancerous deposit? If the former, vaginal hysterectomy is eminently proper. If the latter, vaginal hysterectomy is hardly justifiable; and it is questionable whether the abdominal method will furnish better results.

These cases are extremely hard to differentiate, but when coming in contact with them it has been my custom to operate upon all such as gave a history of former pelvic inflammation, and who were not suffering from the ordinary cancerous cachexia. It is a matter of surprise sometimes as to the thoroughness of the removal of the broad ligaments in these cases by the vaginal route, if we combine the use of the hemostatic forceps with the ligature in cases in which there is great difficulty in controlling the hemorrhage by ligatures alone.

My results in such cases have been sufficiently good to warrant a continuance of operative work in the same direction. It may be that the combined abdominal and vaginal method, as described by Dr. J. H. Clark, resident gynecologist at the Johns Hopkins Hospital, in the July and August (1895) numbers of its *Bulletin*, in which the broad ligaments are very thoroughly removed, will give better results than the vaginal method. I shall be glad to hear the ultimate results of cases operated upon by this method.

In this short *résumé* of my cases I have confined my remarks (with the exception of the one digression just read) to the *ultimate results* in cases in which the disease, as far as could be determined, *began* in the cervix uteri; these cases, as before stated, being but a limited number as compared with all my cases of vaginal hysterectomy for malignant disease. Before closing it might be well to add that in all my cases of vaginal hysterectomy the ureters have escaped injury. In two cases I have had vesico-vaginal fistulæ follow. In one of these the fistula was sewed up some five months after the removal of the uterus, and the patient is in perfect health to-day. The other case, a hospital patient, was one of the three mentioned as having been lost sight of. These statistics, although giving 33⅓ per cent. ultimate success, would have been better still had it not been that my entire death-rate from this operation performed for various conditions during the past twelve years is confined to the three cases among my twelve earlier operations; and these cases happen to belong to the class dealt with in this paper. As stated earlier in the paper I attribute them to faulty technique, prolonged manipulation, and inexperience in performing the operation as far back as tenor twelve years ago.

SCURVY IN INFANTS. WITH REPORT OF A CASE.[1]

By WM. FITCH CHENEY, M.D.,

ADJUNCT TO THE CHAIR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN, AND CHIEF OF THE CHILDREN'S CLINIC, COOPER MEDICAL COLLEGE, SAN FRANCISCO, CAL.

SCURVY is a disease that has been recognized and described since very early times. Soldiers in the army of the Roman Empire suffered from its ravages; and sailors that crossed the Atlantic in the wake of Columbus fell victims to this scourge. In the army and navy of England and the United States, scurvy was for many years responsible for great loss of life, decimating garrisons and rendering long sea-voyages almost impossible. After several centuries of such sacrifice, investigators at last found that the disease was invariably due to a deficiency or absolute lack of fresh vegetable food; also that in lemon juice there existed a simple means, not only of preventing the disorder, but of checking it when it appeared. Following these discoveries, scurvy became so rare that it is now a curiosity in the practice of medicine, with which the majority of physicians never meet.

[1] Read before the San Francisco Medico-Chirurgical Society.

But strangely enough this disorder is within the last decade again coming prominently into notice; and most strange of all, it now makes its appearance, not in soldiers or in sailors, but in babies; not in the camp or on the sea, but in the nursery of homes where no deprivation exists, but plenty and even luxury are found. I have said it now makes its appearance, but I should rather say it is now being recognized; for there is no doubt that many infants have in the past been allowed to die who were suffering from scurvy, but treated for some disorder with which they were never afflicted. That infants do have scurvy was first brought to the notice of the profession by Dr. W. B. Cheadle, of the Great Ormond Street Hospital for Sick Children, London. He first called attention to the fact in a paper published in the *Lancet* in 1878. At various times since then he has continued to report cases, and by his writings other investigators have likewise had their eyes opened to the truth. There is no doubt now that scurvy does occur in infants; that it is due here to the same causes that bring it about in adults; that it presents the same group of symptoms, and that it is susceptible of cure by the same treatment. No textbook on the diseases of children ever mentioned it before the present decade; but in the recent textbooks and in medical journals articles are now freely devoted to its consideration.

Etiology.—What causes this disease in infants? Exactly the same factor that figures in the scurvy of adults, viz., *deprivation of fresh food.* Infants nursed at the breast do not have scurvy; it is a disease peculiar to infants artificially fed. But neither do infants fed upon a proper preparation of cows' milk present symptoms of scurvy, for cows' milk, when fresh, possesses, like human milk, antiscorbutic properties. It is when milk has been long subjected to high temperature, as in sterilization or in condensation, that it loses this antiscorbutic property and becomes no longer fresh. Most fertile, however, of all foods in the production of scurvy in infants are the patent proprietary preparations that are bottled or canned and stand on the shelf for months before they are administered. They are stale, they lack in nutritious properties, and the sailor in Arctic seas or the soldier in garrison fed exclusively on canned meats and hardtack is no more liable to scurvy than the baby fed exclusively on these proprietary foods. It is suggestive, too, that scurvy most frequently occurs in the first eighteen months of life. During the first year, food of but one kind is usually given, and if that kind is bad,

the nutrition is bound to suffer, but after the first year the diet begins to be varied, so that from some of its food the infant receives the needed antiscorbutic elements. Hence the rarity of scurvy in infants over eighteen months of age.

Symptoms.—An infant with scurvy is usually pale and anemic, more or less emaciated, and cross and fretful in disposition. Such symptoms, however, only mean that the nutrition is poor, and are in no way peculiar to scurvy. But there is a group of symptoms that are characteristic—so much so that any one of them creates suspicion of scurvy, and occurring together they render the diagnosis positive.

1. The most peculiar manifestation of the disease is fusiform or cylindrical swelling of one or both thighs. The swelling is evidently painful to the infant when touched or examined, and the limb lies flexed and abducted, or straight and helpless. This condition is due in scurvy to a subperiosteal hemorrhage about the shaft of the femur. The enlargement usually extends from hip to knee, but is greatest about the centre of the thigh. It sometimes involves as well the upper part of the leg, below the knee, but is always less marked there. The superficial tissues of the limb are apt to be edematous, but, owing to the depth of the blood effusion, fluctuation cannot be detected, nor is there discoloration of the surface. This is the symptom that the mother will probably notice first. She observes that her baby cries and frets when it is bathed, or has its napkin changed, and, in searching for a cause of the unusual sensitiveness, happens upon the enlargement of the limb.

2. Another characteristic feature of scurvy is the condition of the gums. If the infant has teeth, the gums will be found swollen, spongy, dark purple in color, bleeding freely on touch, or perhaps covered with dry blood. Such an appearance is so striking that it can scarcely fail to attract the attention of the mother or nurse, and when seen by the physician who knows the symptoms of scurvy, it should make him very suspicious of the presence of that disease. But this condition does not show itself in the infant before the teeth have appeared. The gums then are found entirely normal, or at most display here and there a few ecchymotic spots. It is important to remember that in an infant with no teeth the characteristic spongy gums are not, as a rule, present; forgetting this, one might be led astray on diagnosis by the absence of this peculiar symptom, even though other symptoms of scurvy were plainly present.

3. Equally striking is the occurrence, in a baby too young to have possibly been indulging in fighting, of a typical "black eye." The mother one day notices that there is a dark circle around her infant's eye, as if some one had struck it and made a "black and blue" mark. This gradually fades away and disappears, but the peculiarity may show itself in a few days in the other eye, or may recur in the same eye at varying intervals. It is due to a subcutaneous hemorrhage into the tissues about the eye. This sympton is so strange that if it does not alarm the mother enough to make her summon a physician at once, it will nevertheless impress her so deeply that she will not fail to recall it when asked about the matter. A "black eye" coming on in an infant without traumatism, and perhaps repeated several times, can rarely be due to anything else but scurvy.

These are the most typical and characteristic symptoms of scurvy in infants, but there are others that must be borne in mind. The tendency throughout the disease is to hemorrhage; and this same tendency, that leads to the effusion of blood beneath the periosteum of the long bones, or into the tissues around the orbit, leads also to other manifestations, less frequent, but fully as significant when they do occur. Thus, the hemorrhage may take place into the muscles, causing circumscribed painful indurations; or beneath the skin, causing black and blue spots that look like bruises; or into mucous membranes, giving rise to epistaxis, or blood in the urine, stools or vomited matter. Hematuria may be the only symptom that attracts the notice of the mother and leads her to seek advice, as in a case reported by Cheadle.

Diagnosis.—The disease in question has been most often mistaken for rickets; in fact there are often symptoms of rickets present with those of scurvy, since both are caused by improper feeding. But no rickety child or any other will have scurvy, unless its blood lacks the antiscorbutic principle supplied by fresh food. Emaciation, anemia, fretfulness and irritability, and disinclination to be moved or handled are symptoms as much associated with one disease as the other; and with scurvy there may even coexist beading of the ends of the ribs, enlargement of the epiphyses at wrists and ankles, and the square-shaped head that are charateristic of rachitis. Yet rachitis does not give rise to swellings of the shafts of the long bones, or to spongy gums or to sub-

cutaneous or submucous hemorrhages. It should always be possible, therefore, on close examination, to distinguish between the two diseases.

The swelling and tenderness of a limb accompanying scurvy make one think of acute rheumatism; and histories are not lacking of cases treated for days with salicylate of sodium before a correct diagnosis was at last established. This mistake can arise only from superficial examination, overlooking other conditions of the infant than those present in the limb; and even if the swollen and tender limb were the only symptoms present, there would be lacking the redness of the surface and the elevation of temperature that accompany acute rheumatism.

The disinclination or positive inability to move the affected limb in scurvy has led to the mistake of diagnosing infantile paralysis. But besides the fact that in the scorbutic dyscrasia there are other manifestations besides the condition of the limb, the hyperesthesia of the member and the normal knee-jerk should exclude the diagnosis of infantile paralysis.

Finally, the swollen limb of scurvy has been mistaken for some distinctly local affection, such as periostitis, abscess of the hip or knee, or sarcoma. Dr. L. Emmet Holt, of New York, has reported a case of infantile scurvy, diagnosed as sarcoma by several surgeons, because of a large swelling about the knee; the autopsy showed no sarcoma, but very extensive hemorrhage and epiphyseal separation at the lower end of the femur.

The subcutaneous and submucous hemorrhages noted in scurvy occur also in several other affections, as hemophilia, leukemia, purpura hemorrhagica and erythema nodosum, all of which appear at times in infants and must be remembered in making a differential diagnosis.

In general, most of the failures to properly diagnose scurvy in infants have come from the lack of knowledge that such a disease exists. It has never been clearly brought out until the past ten years, that babies are subject to a distinct disease corresponding to the scurvy of adults. When this fact is more generally recognized by the profession, fewer mistakes in diagnosis will be made.

Prognosis.—The prospect is most brilliant when once the condition is recognized; for while scurvy left untreated is frequently a fatal disease, yet even in the worst cases the response to proper treatment is immediate. As Dr. W. P. Northrup says: "There are two things in a physician's work which may well call out the word 'miracle': one is intubation and instant relief from suffocation, another is scurvy's cure."

Treatment.—The treatment is specific and yet it includes no drugs. It comprises two simple remedies: fresh cow's milk for food and fresh orange-juice. The stale food must be replaced by fresh-milk, modified or not with some diluent, according to the age and condition of the infant. The orange-juice can be given in teaspoonful to tablespoonful doses, three times a day. It is sometimes advisable to add to the diet fresh beef juice, prepared by heating thoroughly a piece of steak and then squeezing out its juice with a lemon-squeezer. No medicine is necessary. The swollen limb as a rule needs no treatment whatever; but if the condition has advanced to separation of epiphysis from diaphysis, the limb should be put up in splints to prevent deformity. The swelling of the gums usually subsides quickly under the administration of milk and orange-juice, but the bleeding from them may require some astringent application, such as the glycerite of tannin.

In conclusion, the following case is reported as typical of the disease in question, both in its clinical history and in its prompt response to treatment. It is also, so far as I can find from the literature on the subject, the first case to be reported from the Pacific Coast: Olive N., female, aged 10 months, was first brought to the Children's Clinic of Cooper Medical College on July 31, 1895. The mother had noticed enlargement of the right thigh; that the digestion was very poor; that the heart seemed to beat too rapidly; that the skin about the left eye had swelled on two occasions recently and turned darker colored, like a "black eye"; that the baby had nose-bleed once recently, and some bleeding of the gums. The enlargement of the thigh was first noticed about three weeks previous, and had gradually increased since. The discoloration about the eye was first noticed about July 17th, and the second occurrence about July 24th. The mother reported further that the baby's appetite was poor; that instead of sleeping, she whined and cried all night, but seemed easier in the daytime; that the discharges from the bowels were acid and very irritating to the buttocks, generally too frequent, and always fluid, and that the disposition was always peevish and fretful. There was a history of artificial feeding from birth. Many foods had been tried in succession, none seeming to digest well. Since November, 1894, malted milk had been used continuously, with a little better result. The mother prepared this

food by adding three teaspoonfuls of Horlick's malted milk to eight tablespoonfuls of water. The baby had just cut her first tooth at ten months, and had never yet made any attempt to stand on her feet. Both parents were living and well. There were three older children living, all well. One child had died of cerebral trouble, and had a history of bow-legs, straightened by operation at two years of age.

Physical examination showed that the infant was pale, poorly nourished, cachectic, the left eye protuberant; complexion fair, eyes blue, hair light, the body much emaciated. There was slight enlargement of the post-cervical glands, a marked rachitic rosary, box-shaped chest, and widely open anterior fontanel. Several small spots of ecchymosis were observed on the gum of the lower jaw on the left side. There was swelling of the right thigh from hip to knee, greatest about the middle, with slight enlargement also below the knee, in the upper third of the leg. The skin over the swelling was very tense, and no fluctuation could be made out. Some pitting of the subcutaneous tissues was observed on pressure. There was no redness of the surface or increased heat in the part, but the limb was apparently painful when handled. The infant made no effort to move the member. The greatest circumferenee of the right thigh was $9\frac{1}{2}$ inches; of the left thigh, 7 inches. Percussion and auscultation showed heart and lungs normal.

The mother was instructed to drop the malted milk entirely, and feed the baby instead equal parts of cow's milk and oatmeal water. The cow's milk was to be allowed to stand for three or four hours, and only the cream and top milk used. The oatmeal water was to be made by boiling for one hour three teaspoonfuls of oatmeal in a quart of water. Of this mixture, four ounces were to be given every two hours. In addition, the baby was to receive one tablespoonful of fresh orange-juice three times a day.

August 3d.—The mother reported that the child had taken the food as directed, regularly and without difficulty. The appetite was much improved. The ecchymosis of the gums, and protrusion of the left eye had entirely disappeared. The swelling below the right knee was markedly diminished, but not noticeably above. The mother was instructed to make the proportions of the food two-thirds top-milk and one-third oatmeal water, and to increase the amount to five ounces at each feeding. The orange-juice was ordered continued.

August 7th.—The infant was reported suffering from constipation, and did not seem to take her food quite so readily as formerly. The interval between feeding was therefore increased to two and a half hours and more cream added to the food. One teaspoonful of fresh beef-juice was ordered with each feeding. If the bowels did not move daily, they were to be relieved by use of the soap-stick. The thigh at this visit was found to measure but 9 inches in circumference.

August 10th.—The baby was much improved, no longer constipated, and with good appetite. The limb was still further decreased in size, measuring only $8\frac{1}{2}$ inches. The food and orange juice were ordered continued as before, except that the beef-juice was to be given only with each alternate feeding.

August 14th.—Continued improvement in all respects was noted. The amount of food was increased to six ounces at each feeding and the interval to three hours. The beef-juice was dropped to one teaspoonful three times a day.

August 17th.—All the general conditions were noted as still improving, the appetite good, the bowels regular and passages well digested, the color better and a perceptible gain in flesh. The tumefaction of the thigh was still receding, and the greatest circumference measured but eight inches.

August 31st.—The infant could now move the affected limb quite freely, and apparently suffered no pain on motion or on handling of it. The greatest measurement was but $7\frac{3}{4}$ inches.

September 18th.—The limb was apparently the same size as the other, and the infant well in all respects and thriving. The orange-juice and beef-juice were discontinued entirely, and the food increased to seven ounces every three hours.

November 20th.—The infant was brought back to the clinic for an acute eczema, but with this exception was entirely well. It had none of the symptoms of scurvy, was rosy and well-nourished and in the best of spirits. Both thighs were the same in size, eaeh measuring just eight inches. The infant was beginning to stand on its feet, and gave every promise of soon learning to walk.

906 Polk St.

Dr. Baxter T. Smelzer, secretary of the State Board of Health, has been investigating into the epidemic of typhoid fever at Elmira. He finds that the water of Chemung river, which is used in the city, is polluted by the sewage of Corning, Hornellsville, and Bath. Ice taken from the river at Elmira was found to be filled with bacteria.

THE AMBULATORY TREATMENT OF POTT'S DISEASE.

BY ROBERT W. LOVETT, M.D.,
OF BOSTON.

POTT'S DISEASE is in itself only a tuberculous destruction of the anterior part of the bodies of the vertebræ. No deformity is necessarily attendant upon its occurrence, and the antero-posterior curvature of the spine, with which we always associate it, is really the result of the erect position. It is said that this deformity does not occur in quadrupeds.

The present paper is an attempt to formulate certain problems which are met in the treatment of this affection by ambulatory means. When a surgeon, in starting to treat a case of Pott's disease by ambulatory methods, selects the force of gravity as his antagonist, rather than as his assistant, it is proper that he should appreciate the problem which he is undertaking and understand clearly the mechanical aspect of the case. Instead of keeping the patient with Pott's disease in bed, if the surgeon allows him to go about, so that the heavy weight of the body comes upon the diseased segment of the vertebral column, the surgeon should know pretty definitely whether this is a matter that he can counteract by apparatus, or whether all mechanical support to the spine is not necessarily imperfect. The question is this: Can the spine be placed in as favorable a condition for recovery as during recumbency, and what is the mechanical value of the methods of ambulatory treatment now in use?

To consider, for example, a case of dorsal Pott's disease in a boy weighing forty pounds, where the disease is located in the lower dorsal vertebræ, say the ninth, tenth, and eleventh. It is manifest that, inasmuch as the vertebral column bears all the body weight, and as the vertebral column is normally convex backward in the dorsal region, the weight of the body above the disease must needs be transmitted through the bodies of the dorsal vertebræ. This weight is the weight of the segment of the body above the diseased vertebræ. It includes the head, with the brain, the neck and its firm muscles, the shoulder girdle, from which hang the arms, which are of no little weight, and the upper part of the chest, with the contained organs. There is no support in front. These organs are hung simply from the backbone, from which the chest girdle runs out just as a crossbar does from a telegraph pole. It is not a bad estimate, I think, to place the weight of these organs which I have just mentioned as half the body weight—in this case twenty pounds. We will assume, then, that the problem in this especial case is to modify, if possible, the pressure which comes from this weight upon the diseased vertebræ, and that this pressure is the result of a twenty-pound superincumbent weight.

The problem which efficient mechanical support must solve is to remove or lessen the weight coming upon the diseased bodies of the vertebræ. The antero-posterior brace attempts to do this by acting as a lever which shall transfer the weight to the articular and transverse processes by pushing against the deformity as a fulcrum. In other words, it should modify intervertebral pressure. It is upon this theory that the brace was constructed and should be used.

The model which is presented is a very imperfect affair, but one which makes very clear some of the intrinsic difficulties met with in the treatment of Pott's disease. This model was made as follows: A plaster jacket was applied to a patient and removed. After removal, the jacket was bandaged together and filled with plaster-of-paris paste, which hardened into a rough cast of the trunk. This cast was sawed in halves transversely, and by putting in some blocks of wood at the back to represent the vertebræ *H*—if these two halves are placed as shown in the picture, the conditions of a case of mid-dorsal Pott's disease—are fairly well represented (1). A Taylor back brace is applied by being bandaged to the lower segment and running up just as it would in the case of a patient. It is made to exert force at

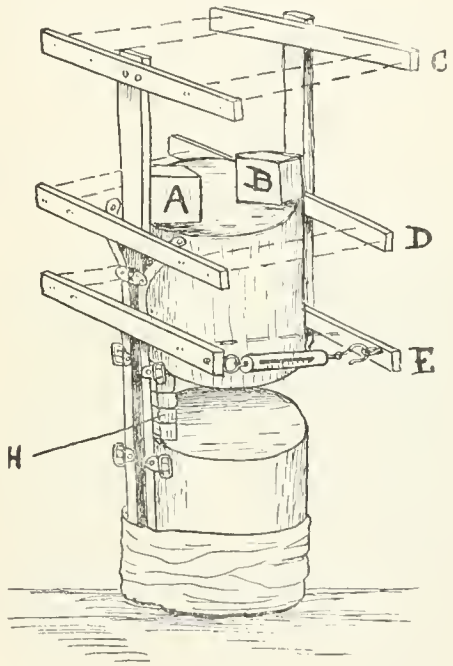

FIG. 1.

the point represented by the blocks of wood just as it would press forward upon the deformity. The upper part of the brace is bandaged to the top segment. These two segments of plaster represent the two segments of the body above and below the disease, and the problem is to determine what force must be applied by the brace to keep these segments in place. This would correspond to the force required to modify the intervertebral pressure, and this modification of the intervertebral pressure should be what the surgeon should strive to accomplish in all cases of Pott's disease treated by this brace.

The criticism may be made that this model does not reproduce the muscles. The only muscles which come in question are the intrinsic muscles of the spine, and those work to such a very great disadvantage in comparison with the leverage that the weight obtains, that they may be disregarded as of practically little importance. They could have been represented by rubber cords running along the back of this model, but it is evident that such apparatus would have very little practical influence upon the experiment. The posterior muscles of the trunk may tilt the body backward, as often happens, but this acts only to bring the superincumbent weight further back, and will be discussed later.

The upper part of this model weighs ten pounds, and a ten-pound weight is attached to it, which represents fairly well the conditions in a case of dorsal disease in a boy weighing forty pounds. An arm runs out from the back brace and other arms run out from the front of the upper part of the model. These are connected by spring balances, which show how much pressure is required at different levels. They show how much force will be required to hold the upper part of the model back.

Three things can be demonstrated by this model: (1) If the chest is firmly held, and the pelvis is held with equal firmness, the pressure coming upon the spine over the disease, in case the brace were used to modify intervertebral pressure, would be so great that no skin would be able to stand it. If the finger is placed between the back brace and the wooden blocks in the model which represent the diseased column, it will be found that even when the upper segment only weighs twenty pounds the pressure cannot be borne. It simply demonstrates the necessarily incomplete action of the brace, for if it were possible for the pelvis and chest to be held as firmly to the brace in the living subject as in this model, the skin would not be able to stand the pressure. It is obvious that the pelvis and chest cannot be held as firmly as in this model. (2) The position of the superincumbent weight is a most important matter. If the ten-pound weight is placed at *A*, that is as far back as possible, the spring balance at *D* registers ten pounds. If, however, the weight is placed at the forward part of the model, *B*, the balance registers nearly twenty pounds, demonstrating that the position of the superincumbent weight (that is, of the head and shoulders) is a most important matter in determining the amount of weight to come upon the diseased vertebræ. Therefore, if the head and shoulders are held as far back as possible in this way, it requires much less pressure to make the brace efficient than when the head and shoulders droop forward. (3) The level at which the backward pull is applied is a most important matter. In this experiment the spring balances are adjusted at the level of the axillæ, *D*, and the transverse pull is made practically at the level where would come the highest transverse straps of the apron. If the pull is made at a lower level in the model *E*, so great an amount of force is required to hold the upper part of the model in place that it cannot be registered by the balances in use. If the two arms are prolonged up to what would perhaps be the level of the middle of the face, *C*, much less force is required to hold the upper segment of the model in place than when pressure is made backward at the axillary line; that is, the higher the backward pressure is applied the less force is required to hold the upper part of the model in place.

This model is not presented as an accurate reproduction of the mechanical conditions in Pott's disease, but to demonstrate certain obvious facts.

The practical application of this experiment is as follows: In the living subject it is not possible to obtain a sufficiently firm hold upon the chest and pelvis. If it were, the skin over the deformity would not be able to stand the force required to modify intervertebral pressure. The Taylor back brace as ordinarily applied exerts no backward pull above the axillary line, where a very great force would be required to pull the upper segment of the body backward (Fig. 2). The chest piece of Dr. Taylor, which applies backward pressure in the fossæ under the clavicles, is in the right direction. The apparatus of Dr. Whitman (Fig. 3), which makes pressure upon the anterior part of the shoulders, is also in the right direction, but incomplete and incapable of exerting proper pressure. If a firm hold could be obtained upon the chest, a brace would be able to accomplish much more

than is found to be the case now. The chest piece used by the writer, which is practically an anterior brace to the chest, is shown in the diagram. It is an effort in the direction of obtaining this hold upon the chest, and is partly satisfactory.

Fig. 2.

With regard to the mechanical efficiency of the plaster-of-paris jacket in Pott's disease, a different method of experiment was undertaken. If the plaster jacket diminishes the deformity, or extends the spine when applied, it must necessarily cause lengthening of the body. If the plaster jacket can accomplish as much, or nearly as much as is done by having the child lie on its back, the length of the child should be as much after the application of the plaster jacket, as when lying down. Some preliminary experiments were made with regard to the effect of recumbency in increasing the length of children with Pott's disease. (1) A boy with lumbar deformity was one-quarter of an inch longer when lying down. (2) A girl with dorsal deformity was one-half of an inch longer when lying down. (3) A girl with lumbar deformity was one-quarter of an inch longer when lying down. (4) A girl with acute dorsal disease was seven-eighths of an inch longer when lying down. (5) A girl with high dorsal disease was seven-eighths of an inch longer when lying down.

These experiments show that a child with Pott's disease is from one-quarter to seven-eighths of an inch longer in recumbency than in standing. This difference can be accounted for by the change in the curves of the spine.

An experiment was then undertaken to see if the plaster jacket caused lengthening of the child, and if so, under what circumstances. (1) Jacket applied by suspension. The immediate effect was an increase in the length of the child five-eighths of an inch over the standing position, but at the end of twenty minutes the child had shortened three-eighths of an inch, and at the end of thirty minutes was back to one-eighth of an inch of the height when standing with no apparatus. In other words, the application of a plaster jacket lengthened the child only one-eighth of an inch. It may be mentioned incidentally that the child when lying on its back was one-half of an inch longer than when it was standing up with a properly applied plaster jacket. (2) A jacket was applied to a child, with the effect of immediately lengthening it over the standing position. At the end of twenty minutes, the child was at the same height as when standing without the jacket on, and was seven-eighths of an inch shorter than when lying on the back in bed. The jacket was

Fig. 3.

applied by suspension. (3) A jacket was applied by the hammock method: Standing without support, 3 feet $2\frac{3}{4}$ inches; ten minutes after application of jacket, 3 feet $2\frac{3}{4}$ inches; twenty minutes after application of jacket, 3 feet $2\frac{1}{2}$ inches. (4) Jacket applied by the hammock: Standing with-

out jacket, height 3 feet $4\frac{5}{8}$ inches; immediately after application of jacket, 3 feet $4\frac{3}{4}$ inches; ten minutes after application of jacket, 3 feet $4\frac{5}{8}$ inches.

In no one of the four experiments was the child substantially longer after the careful application of the jacket than when standing unsupported, and in no case as long as when lying down without apparatus. The column is longest and the spine consequently straightest when the child is suspended or has traction applied in bed to the legs and head. A boy with mid-dorsal disease, not very acute, was an inch longer in bed with traction than when he stood up. A girl with high dorsal disease and paralysis was lengthened three-eighths of an inch by traction over her length when lying quietly in bed. The spine is in its second best position when the child lies in bed without traction. The spine is shortest, and consequently in its worst position when standing, and the application of a jacket has not, in any case observed by the writer, been found to produce any permanent increase in height, except in one case where it lengthened the child one-eighth of an inch over the position without a jacket. The same may be said of the application of the antero-posterior brace. Recumbency, on the other hand, does produce such an increase in length. To the writer's mind, the case is clear. Recumbency with traction is the best available treatment if we regard only the position of the spine. Simple recumbency is the next best. Treatment by ambulatory measures is the worst. These are demonstrated by the length of the child under these various conditions.

Recumbency: With regard to the treatment by recumbency I am as far as any one from wishing to advocate unnecessary recumbency, but I wish to go on record as advocating, in general, during the acute stage of Pott's disease, recumbency on a frame for the greater part of the time, varied by short periods of going about protected by the most available brace or jacket. During the painful stage I believe that recumbency should be continuous. The beneficial effect of recumbency must be familiar to every orthopedic surgeon, who must often notice the improved appetite, the increase in flesh, and the diminished fever, when a child with acute Pott's disease is put to bed.

In the use of apparatus it should be remembered that it is all necessarily imperfect from a mechanical point of view, and does not afford complete support, and that traumatism to the spine must result from the use of the jacket or the brace. The more complete and efficient the apparatus, the less the traumatism.

Such are the scattered facts that I have brought together for your attention. Pott's disease, it seems to me, is a very grave affection, and in advocating its treatment by recumbency, rather than by ambulatory measures, during the acute stage, I am speaking of what I believe to be the very best treatment. Other modes of treatment are no doubt excellent, but when one wishes to secure the very best result, it seems to me that, having recognized that apparatus is intrinsically imperfect, and necessarily so, to accomplish the purpose for which it is intended, it is incumbent upon the surgeon either to insist upon this treatment by recumbency or to transfer the responsibility of ambulatory treatment to the parents. The use of apparatus, it seems to me, should be during the acute stage, to vary the monotony of recumbency. That recumbency should be carried out by having the child lie upon its back upon a frame. The addition of traction to the legs and head I believe to be of benefit, and that it hastens recovery by quieting muscular spasm and improving the position of the spine. I believe that it should be used in all cases of paralysis due to Pott's disease.

With regard to apparatus, whether we use it in the way that I have advocated or as the sole means of treatment, it seems to me that we should remember that apparatus is necessarily mechanically inefficient to solve the problem which it undertakes. If apparatus is used these points should be remembered: the position of the superincumbent weight should be as far back as possible; and the higher the backward pull comes, whether a jacket or a brace is used, the less force is required.

Whether we wish to follow the best treatment or not may be a question, but it is the writer's belief that treatment by recumbency, so prevalent in the early days of orthopedic surgery, will come again to the front if the real value of supporting apparatus is studied.

THE DIAGNOSIS OF GASTRIC CARCINOMA.[1]

By ALLEN A. JONES, M.D.,
OF BUFFALO, N. Y.,
INSTRUCTOR IN PRACTICE AND CLINICAL INSTRUCTOR IN MEDICINE, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

Carcinoma of the stomach usually occurs after the age of 35, although it may occur before; indeed, it has been recorded in infancy. Heredity is not as important a factor in diagnosis as was formerly taught. In some parts of the coun-

[1] Read before the Surgical Section of the Buffalo Academy of Medicine, January 7, 1896.

try carcinoma is more commonly seen than in others, and Roswell Park has remarked upon the frequency of its occurrence in the vicinity of western New York. Sex does not seem to have much influence upon the frequency of carcinoma.

The history of the illness should be carefully considered, for it is difficult to determine just when the disease commences, the early symptoms depending in a measure upon the location of the neoplasm. If it arises at the cardia, symptoms pointing toward obstruction at that point may develop very gradually. Some trouble in swallowing may be experienced. A few mouthfuls of food are swallowed and then the patient feels a vague distress beneath the sternum which is accompanied or followed by regurgitation of food. Pain may be present, but is not constant as is ordinarily supposed. In case the fundus of the stomach is the seat of an extensive infiltration which gradually leads to thickening and contraction, the early symptoms may consist of distress after eating, amounting in some cases to severe pain; or nausea and vomiting may occur after small quantities of food have been eaten; the capacity of the stomach in these cases steadily diminishes, and a few ounces of food serve to tax it quite fully. The symptoms and physical signs of carcinoma in this location differ markedly from those of carcinoma of the pylorus. The diagnosis in some instances is very difficult, as there may be no symptoms referable to the stomach. In those cases having the disease situated at the pylorus the early events usually indicate ischiochymia. Constipation is noticed, and at long intervals copious vomiting occurs. Food stagnation manifests itself by the appearance of substances in the vomitus that were eaten one or more days before. Marked gastric discomfort or actual pain, accompanied by nausea, usually preceeds these vomiting spells, and immediate relief is experienced as soon as some of the stomach contents are expelled. As a rule only a portion of the contents is vomited, it being a rare occurrence for the stomach to be thoroughly emptied in this condition by the act of vomiting.

At first these attacks happen only once in one or more months, but they occur more frequently as time passes and the pyloric stenosis increases, until finally food is rejected after every meal, perhaps, or vomiting occurs regardless of eating.

The time elapsing between the earliest and the latest manifestations of malignant disease of the stomach depends somewhat upon its location. When it is situated so as to interfere with the onward passage of food from the esophagus through the stomach and into the duodenum, loss of flesh and strength makes rapid strides, and a few months may suffice for the appearance of great emaciation and profound debility. This is true because the intestine does not receive the food, and the body is deprived of the manifest advantages of intestinal digestion: the consequent inanition is practically the result of starvation.

In cases with diffuse carcinoma of the fundus, diminishing the capacity of the stomach, but not offering any obstruction to the entrance of food into the intestine, loss of weight may be very gradual, and a fair amount of strength is maintained for a considerable period. The natural resisting power of the patient is an important factor in determining the length of time he will live, as is also the existence or absence of malignant disease of organs apart from the stomach.

The cachexia is not characteristic; it is not different from that occurring in other exhausting affections, nor is it an invariable occurrence. It may appear early and be very marked, but, on the other hand, it may not be noticeable until very late in the disease. All the symptoms are usually progressive.

Among the symptoms mentioned above will be those accompanying the general debility, such as weak pulse, pallor, dry, harsh skin, hyperlithuria, periodic albuminuria, or indicanuria. Sometimes a few hyaline casts are found in the urine. The urea excretion is low, but no more so than is the result of starvation, emaciation, and lowered vitality. The skin may assume an icteric hue, owing, perhaps, in some instances, to blood changes as well as to slight biliary obstruction. Most commonly, however, hepatic jaundice results when the disease involves, by extension, the biliary passages or embarrasses them by pressure.

Examination of the blood shows early a chlorosis, and later the red blood-corpuscles are reduced. Sometimes the red cells fall as low as 1,000,000 per cubic millimeter, and many megalocytes, microcytes, and macrocytes are seen. Normoblasts are also present in some cases. No leucocytosis is observed unless inflammation or ulceration takes place.

By physical examination it is not always possible to detect tumors involving the stomach. The cardia may be seriously affected and no tumor be discernible—the fundus may be thoroughly infiltrated, and yet no tumor palpable; while at the pylorus it is not difficult to discover induration if the disease has progressed far enough and the liver does not overlap the growth. In the presence of very thick or rigid abdominal

walls its detection may be rendered difficult and somewhat uncertain.

Gastrectasia almost invariably occurs and will be discovered by the physical signs of that condition. When gastrectasia results from pyloric obstruction, the steps in the process are analogous to those observed in dilatation of the heart from obstructive disease; in other words, there occurs first excessive demand upon the muscular tissue of the organ, which hypertrophies in compensation; later this compensation fails and true dilatation follows. Sometimes it is possible to make out enlarged lymphatics in the retroperitoneal tissues or in the mesentery; or the left supraclavicular gland may be enlarged.

On the whole, the discovery of a manifest pyloric tumor with gastrectasia, together with the stomach symptoms before mentioned and the general manifestations of the local disease, strengthens one's belief in the existence of carcinoma ventriculi, but an unequivocal diagnosis should not be made without the very valuable and confirmatory evidence obtained by the direct examination. In some cases very valuable information may be elicited by the simple passage of the tube; for instance, in case of carcinoma of the cardia, the tube may meet with an obstruction about fourteen inches from the teeth, and, if esophageal dilatation exists, contents lodged above the cardia may be withdrawn and examined. No hydrochloric acid will be found; there may or may not be lactic acid; no biuret reaction will be obtained unless predigested albuminoid food has been eaten; the acidity will be very low, if present at all. Or it may be found that the tube withdraws the solids best when introduced an unusually long distance, say 28 or 30 inches from the teeth, indicating extensive dilatation of the stomach.

Gastrorrhagia may take place and a large amount of blood be vomited, but this is a rare occurrence. Disorganized blood may be present in the contents, often resembling "coffee-grounds." Red blood-cells may be entirely disintegrated, but the test for hemin crystals may be positive. Fragments from the surface of the carcinoma may be discovered, and cell-nests revealed by the microscope. Usually considerable thick, tenacious mucus is present. Sarcinæ are not so frequently found as in benign pyloric stenosis with gastrectasia. A very large amount of foul-smelling, dark, stagnant contents may be withdrawn, containing remnants of food eaten days before. Such contents almost always indicate pyloric stenosis, and would not be expected in a case of malignant disease of the fundus. Acidity is usually very high; in many cases it reaches 120, requiring 12 c.c. of decinormal sodium-hydrate solution to neutralize 10 c.c. of stomach contents. The acidity depends in most cases upon organic and combined acids, lactic acid being present in unusual quantities.

Hydrochloric acid is absent as a rule, but a few cases have been observed in which it was present until late in the disease. The absence of hydrochloric acid has long been known to be of slight significance as an evidence of gastric carcinoma, but the presence of hydrochloric acid was considered highly conclusive evidence that no malignant disease existed. Unfortunately, this diagnostic prop has been taken away by the indisputable cases in which hydrochloric acid has been present. A case which I observed, and repeatedly examined, was reported by Dr. Charles G. Stockton,[1] in which hydrochloric acid was found with a large visible and easily palpable pyloric carcinoma. Dr. Park performed gastro-enterostomy upon this case.

The chief interest now lies in the question of the presence of lactic acid and lactic-acid-forming micro-organisms in the stomach contents of carcinoma ventriculi.

Lactic acid must be considered under two distinct headings: First, its occurrence under normal and various morbid conditions on ordinary diet, or when introduced preformed into the stomach; second, its formation in the stomach after food absolutely free from lactic acid has been eaten.

In 1892 Martius and Luttke showed that lactic acid was not a normal constituent of the gastric contents. Prior to that time the dictum of Ewald and Boas, that lactic acid was present in the normal stomach for about thirty or forty minutes after Ewald's test-breakfast of a roll and water, was accepted. Boas investigated the subject thoroughly, and in 1893 announced that the confusion arose because all products of the bakery contained an appreciable amount of lactic acid. Boas was dissatisfied with Uffelmann's test, and he devised a new and elaborate method for the detection of lactic acid. This method is based upon the fact that manganese dioxide and sulphuric acid decompose lactic acid, forming acetic aldehyd and formic acid. Boas' test conducted as a qualitative examination is as follows: The gastric contents are filtered, and 10 c.c. of the filtrate are tested for the presence of free

[1] New York State Medical Association meeting, October 15, 16, 17, 1895.

acids by Congo red; if free acids are present, an excess of barium carbonate is added. The contents are then evaporated in a porcelain capsule over a water-bath, to the consistence of syrup. The carbon dioxide is driven off by boiling with a few drops of phosphoric acid. The further directions are, cool and treat two or three times with 50 c.c. of ether that is absolutely free from alcohol; digest with the ether half an hour, evaporate, and dissolve the residue in 45 c.c. of water; put this into a flask and add 5 c.c. of sulphuric acid and a small quantity of manganese dioxide. A bent glass tube connects this flask with a mixture of equal parts of one-tenth normal iodine solution and one-tenth normal sodium-hydrate solution, making an alkaline iodine solution. The flask is now carefully heated, and as soon as boiling occurs the iodine solution becomes slightly smoky and the odor of iodoform is detected if lactic acid is present.

Boas devised a test-meal, consisting of a tablespoonful of oatmeal flour to a litre of water, which may or may not be flavored with a little salt. The stomach to be examined is washed out thoroughly at night and the test meal given. The contents are withdrawn in the morning and examined for lactic acid after the manner described. Boas found by this method that lactic acid was never present at any stage of normal digestion, nor was it present in any abnormal condition of the stomach excepting carcinoma, in which disease it is almost invariably present in large quantities. Cases of cancer may exist in which no lactic acid is found. On ordinary diet lactic acid is usually present in larger quantities than are found after the flour-soup test-meal.

In an admirable review of Boas' work D. D. Stewart[1] points out the absolute importance of eliminating from consideration all test-meals in which lactic acid exists preformed. Dr. Stewart emphasizes the particular necessity for exact technique, and says his experience accords entirely with that of Boas. Stewart also speaks of the unreliable nature of Uffelmann's test.

In a series of articles upon "The Early Diagnosis of Carcinoma of the Stomach, with the Bacteriology of the Stomach Contents,"[2] Fenton B. Turck says he finds that lactic-acid-forming micro-organisms are present in abundance in the stomach when carcinoma exists. In no other affection are they so numerous.

In an excellent article, entitled "The Significance of the Presence of Lactic Acid in the Stomach,"[1] Julius Friedenwald carefully reviews Boas' work and gives the results of his investigations. In twenty-nine examinations made, in eight normal cases using the Boas technique in detail, no lactic acid was found. In four cases of superacidity, none was found. In twelve examinations upon eight cases of atony, in but one was any lactic acid found, and then only the faintest trace, that might be accounted for by swallowing lactic acid from the mouth. In two cases of non-malignant dilatation, in one of which hydrochloric acid was continually absent, no lactic acid was present. Twelve examinations in eight cases of chronic gastritis, with hydrochloric acid absent in all, resulted in finding no lactic acid, except in mere traces in one case (probably swallowed). Four cases of secondary gastric catarrh, with hydrochloric acid absent, had no lactic acid. In four cases of gastric carcinoma, with an absence of hydrochloric acid, lactic acid was found in all and at every examination. Friedenwald therefore confirms Boas' statements.

Besides the germs that form lactic acid in culture media, one other, called the faden bacillus,[2] has been found. This is a long, delicate, thread-like bacillus found in the stomach in carcinoma, and in no other disease, which has never yet been cultivated. Its presence is highly diagnostic of carcinoma. Kaufmann first found it in the gastric contents; Boas describes it in the 1895 edition of his work on "Diseases of the Stomach." Julius Ullmann found it in one of our cases without palpable tumor or perceptible dilatation, but with lactic acid present and some food stagnation. There are cases in which hydrochloric acid is present; and in some of these, even though dilatation and food stagnation occur, lactic acid is not found. Such a case was the one before mentioned, which was reported by Dr. Stockton. In this case lactic appeared as soon as free hydrochloric acid disappeared, and it persisted thereafter.

In a few cases Boas' method has given me valuable assistance in excluding carcinoma, and in a few cases I have been, by its assistance, better able to make a provisional diagnosis early and while yet no tumor was palpable. Max Einhorn says[3] Boas' lactic-acid test is of great value, but there are cases in which the constant appear-

ance of lactic acid is observed, and still no cancer exists, also cases of carcinoma without lactic acid. Einhorn cites a case of each kind.

Under normal conditions the rennet-ferment may be present in dilutions up to $\frac{1}{40}$, and the rennet-zymogen up to $\frac{1}{1\,5\,0}$. In diseases of the stomach attended by little or no organic change the zymogen may be present up to $\frac{1}{6\,0}$ to $\frac{1}{1\,5\,0}$, although with an absence of hydrochloric acid the ferment may be reduced $\frac{1}{1\,5}$ to $\frac{1}{5}$. In chronic gastritis and carcinoma the ferment may be entirely absent, while the zymogen is markedly diminished; in the former disease as low as $\frac{1}{3}$, in the latter $\frac{1}{4\,0}$ to $\frac{1}{1\,3}$, or lower according to the extent of the disease. Therefore, the amount of zymogen present affords some information as to the existence of organic disease. J. Friedenwald[1] has studied the matter carefully, and the above figures are taken from his findings.

The gastrodiaphane, devised by Max Einhorn, assists the inventor in diagnosticating malignant disease of the stomach. In cases where the growth thickens the anterior wall, its transparency is diminished and a dim light is seen in that situation, whereas over other parts of the illuminated stomach the light is transmitted with intensity. Dilatation of the organ is certainly made out and that is an important fact. I have used the instrument occasionally during a period covering about three years, and consider it a very valuable addition to our armamentarium.

It is to be hoped that in the future we may be able to make an early diagnosis, before any tumor or dilatation is manifest, so that surgical intervention may reap better results and lives may be greatly prolonged or saved.

436 FRANKLIN ST.

CLINICAL MEMORANDA.

A CASE OF TRAUMATIC OPHTHALMOPLEGIA.[2]

BY DAVID WEBSTER, M.D.,
OF NEW YORK.

ON the 17th of November, 1895, Edward F. McC., aged 6, while walking with a slate-pencil in his hand, stumbled and fell on a board sidewalk. He was picked up in a semi-unconscious state and taken home. Dr. Edward L. Bull was called to see him soon after the accident, and found ptosis, with total ophthalmoplegia of the right eye. There was a punctured wound beneath the right orbital edge, at about the junction of its middle and inner thirds. Besides this wound of the upper part of the eyelid, which was still bleeding, there was a slight bruise or mark on the brow, as though it had struck upon the pencil lengthwise. Dr. Bull examined the parts carefully, but could find no foreign body. On testing the vision of that eye, the boy counted fingers and recognized a watch, but it is now doubtful if he saw the fingers with the *injured* eye, and the loss of sight may have been immediate. It is certain he had no perception of light in the eye a few days later. He looked pale and felt sick, and vomited from time to time for forty-eight hours after the accident. He then recovered his usual health and went about his play as usual, and has been well, so far as his general health is concerned, ever since. Dr. Bull sent him to me a few days after the accident. I found total blindness of the right eye, with absolute ophthalmoplegia and ptosis. The third, fourth, sixth, and optic nerves were totally paralyzed. Ophthalmoscopic examination showed nothing abnormal in the media or in the fundus. It was thought there was slight exophthalmus at first, but I was not sure there was any when I saw him. He has had no pain in or about the eye at any time since the injury, and there have been no indications for treatment.

When I saw him on January 8, 1896, there had developed a slight paleness of the right optic disk. He had also recovered the power to raise his right upper lid a very little; otherwise, the *status* remained unchanged. There is now not only well-marked atrophy of the optic disk, but a neuro-paralytic keratitis has developed itself. The eyeball is slightly red and the cornea is hazy and anesthetic.

The problem in this case is as to the *nature of the injury*. It seems to me most probable that the slate-pencil entered the orbit, injured the lenticular ganglion, and fractured the walls of the orbit at or near its apex. The pencil may still be partly in the orbit and partly in the cranial cavity. I presume the same symptoms could have been brought about by fracture of the orbital walls from the force of the blow of the brow upon the board sidewalk, and possibly even by shock or concussion; but the punctured wound seems to indicate that a portion of the slate-pencil is embedded somewhere in the orbital tissues so deeply as not to be felt with the finger.

CASES ILLUSTRATING VARIOUS PATHOLOGICAL STAGES IN INFLAMMATORY PELVIC DISEASE.[1]

BY LOUIS FRANK, M.D.,
OF LOUISVILLE, KY.,
ASSOCIATE PROFESSOR OF OBSTETRICS AND DIRECTOR IN THE BACTERIOLOGICAL LABORATORY IN THE KENTUCKY SCHOOL OF MEDICINE.

THE cases I report illustrate very well the different conditions we find in inflammatory pelvic affections as a result of tubal diseases. The first of this series was operated upon to-day, the patient being a girl aged 18 years, having the following history:

Two months ago when I first saw the patient she had had an abortion resulting in incomplete expulsion of the membranes, followed by fever, a great deal of abdominal tenderness, and metrorrhagia. Her menstruation up to

[1] THE MEDICAL NEWS, June 22, 1895.

[2] Reported to the Section on Ophthalmology of the New York Academy of Medicine, Jan. 20, 1896.

[1] Reported to the Louisville Clinical Society.

that time had been perfectly regular, with the exception of about ten months ago, at which time she missed one period, which was followed by severe flooding, probably also an abortion. However, there was never any pain, either preceding, during, or after the menstrual epoch. Her menstruation was normal. She denied ever having been pregnant, but the evidence was unmistakable. She could not account for her flooding, nor could she account for the absence of menstruation for two months preceding the time at which I saw her.

Examination revealed an abdomen moderately distended, rather tender to pressure, which tenderness was exquisite over the ovarian regions. There was considerable bleeding, consisting largely of clots. Bimanual examination showed the uterus to be enlarged, tender, and more or less fixed in a slightly retroverted position. The ovaries were very tender; the tubes feeling somewhat hard were very easily mapped out, much more so than common, and there seemed to be no adhesions. She had some elevation of temperature.

I curetted her thoroughly, gave an intra-uterine douche of bichloride solution, and introduced a uterine drain of gauze, which was removed after forty-eight hours. This was followed by douching with plain hot water; she had been thoroughly purged; the distension disappeared, but there remained considerable tenderness about the abdomen.

She convalesced fairly well, and in several days was out of bed. I saw no more of her until three or four days ago. She told me then that since she had been up she had never felt perfectly well, though for a short while she had not much trouble, still with the advent of her menstruation again her trouble had been worse. She had constantly severe abdominal pains, which at the time of her menstruation were almost unbearable. She had been compelled to remain in bed on account of the severity of this pain. She had taken morphia at intervals, could hardly go about, had begun to lose flesh, had lost appetite completely, and presented in other words those symptoms which we find so characteristic in inflammatory pelvic trouble.

I examined her very carefully, finding the uterus retroverted, not freely movable, ovaries and tubes very tender and fixed in adhesions. The tubes, I thought, were somewhat enlarged. I advised waiting awhile, but she insisted that something should be done for her.

To-day I operated by the abdominal route. I found the uterus adherent, as I had suspected, these adhesions consisting of long bands not dense in character, such as we find in chronic inflammatory trouble, but easy of separation. They were separated very carefully. The tubes and ovaries were embedded in adhesions, the intestines being adherent over them upon the right side. After some careful manipulation these were separated. Upon the left side the ovary and tube were also adherent, the fimbriated end of the tube passing out from these adhesions and being attached to a coil of intestine almost on a level with the umbilicus. She had had considerable pain at this point. The ovaries were not enlarged; one of them presented a hemorrhagic cyst, possibly a ruptured Graafian follicle, but the disease was not at all sufficient to justify their removal. The same may be said of the tubes, which, though embedded in these adhesions and showing that they had been the source of infective peritonitis, did not contain any pus. There was a small amount of serum in each tube. The tubes were milked toward the uterine end, then toward the distal end, this secretion being carefully sponged out. The fimbriae were all separated, the tubes and ovaries being allowed to fall back into the cavity, the omentum being packed down around the intestines, separating them completely from the pelvic cavity. The abdomen was then closed with silkworm-gut in the usual manner. I expect the patient to get well without the least trouble.

Case 2.—The second case was operated upon about two weeks ago. Her history is somewhat similar to the preceding one, in detail being as follows:

The patient, S. R., aged 25 years, was referred to me a month ago by Dr. Sieffert for a left pyosalpinx. Four years ago she had had an abortion; though previously always in excellent health, had since had trouble with each menstrual epoch, and of late during the interval between her menstrual periods. This trouble consisted of bleeding, with pain during and also preceding the flow. Lately she had had metrorrhagia. She had never been pregnant except on this one occasion four years ago. There was constant pain in the back and hips, also servere abdominal pain, and she was compelled to remain most of the time in bed.

A careful examination under chloroform revealed an enlarged ovary upon the right side with considerable thickening about the tube; on the left side a great deal of induration and thickening, but no distinct tumor mass could be made out. The uterus was enlarged and not perfectly movable, and there was a purulent discharge from the cervix. She being very anxious to have children, and thinking that she might possibly be benefited, at least to some extent, with something less than an abdominal section, curetting was advised and carried out, from which she recovered without any trouble whatsoever. There was no improvement in her symptoms, and at the first menstrual period after the curetting all symptoms were, if anything, increased in character. She at last consented to a celiotomy, and upon section there was found an adherent uterus with adhesions of the ovaries and tubes to surrounding structures. Both ovaries were enlarged, the right much more than the left. The tubes showed that condition known as hydrosalpinx, the one upon the left side being about as large in diameter as the index-finger, the one on the right side possibly the diameter of the little finger. The adnexa of both sides were removed; the abdomen sponged out thoroughly and closed in the usual manner.

She had for the first week no trouble whatever, but after removal of the stitches she began to complain considerably, and an examination of the abdomen showed formation of stitch abscesses. These were opened and thoroughly washed out, and treated as we usually treat such abscesses.

Case 3. — The third case was operated upon five

weeks ago. The patient, aged 30 years, was referred to me by Dr. Dunn. Her history is that she had been in perfect health until a week before I saw her, when she was seized with sudden pain in the abdomen, so severe that she was at once compelled to take to her bed. A rapid swelling appeared; she became unconscious, and was resuscitated by some of her friends. About the same time she began to menstruate. Dr. Dunn did not see her until two days after the symptoms which I have just cited. He found a large tumor completely filling the pelvis and bulging into the vagina.

When I saw the patient she was having some fever, a very rapid pulse, abdomen very much distended, obstinate constipation, menstruation still going on, though scanty. A positive diagnosis was very difficult to make on account of the meagre history which was obtainable. Dr. Dunn and I, after a thorough examination, finding this large tumor completely filling the pelvis above and bulging into the vagina to such an extent that the index-finger could hardly go by it, concluded that our patient had one or two things—either she had an extra-uterine pregnancy which had ruptured into the broad ligament, or she had an old pelvic peritonitis, which had been relighted by leakage from the pyosalpinx into the peritoneum. Though the patient's history pointed more to an extra-uterine pregnancy, still her condition, character of the tumor, and the absence of all signs of pregnancy inclined us rather to the latter opinion.

She was sent to the Infirmary with a temperature of 101° F. and a pulse of 124. Operation revealed upon both sides immense tubo-ovarian abscesses, which were simply enormous, and upon one side extended down into the pouch of Douglas, forming the mass which we had felt in the vagina. This mass did not have a fluctuating feel. This was due to the great amount of inflammatory deposit around the tumor. The tumors completely surrounded the uterus above, in front, and below, and it was necessary to separate them very carefully to prevent injury to the bladder and intestines. After separating the numerous and dense intestinal adhesions above, the tumor on one side was removed, though in doing so it was ruptured, allowing fully a quart of pus to flow out, a large portion of which escaped into the abdominal cavity. In like manner, in removing the tumor from the other side, pus escaped into the cavity, though this was not due to rupture in the removal of the tumor, but to one which had existed before removal of the tumor, as shown by an abscess sac formed of the tumor upon one side and of the parietal peritoneum upon the other. All in all, more than two quarts of pus escaped. The abdominal cavity was thoroughly washed out with sterilized water, a drainage-tube was inserted, and the patient put to bed. For several days she was in a precarious condition; however, as her bowels began and continued to move freely, and we persisted in the use of stimulants, we had the pleasure of seeing her pulse gradually decrease and distension disappear, until now she has gone on to a good recovery, there remaining, however, a fistulous tract at the site of the drainage-tube. This fistula will probably remain until finally the ligatures, which were put upon the ligaments on one or both sides, and which have no doubt become infected, suppurate and come away.

These three cases illustrate very beautifully the several steps in one of the commoner inflammatory pelvic troubles. The first case, if it had been left alone, would have gone on to, first, hydrosalpinx, then pyosalpinx, later possibly tubo-ovarian abscesses, such as in the last case reported. Case 1 shows what can be done by early operation—extensive and dangerous adhesions may be prevented, as may also the formation of pus with its attendant dangers, and our patients undoubtedly have a far better chance of recovery than in those cases that are "tinkered" and allowed to go on until they have reached the condition in which the last patient was found. The first case was the simplest of the three. The second case, which shows the next step in the development of pus-tubes, was much more simple and much easier for the operator, and the outlook better for the patient, than the last case; at the some time the adhesions were dense, and infection had evidently been more severe and longer continued than in case 1. The earlier we can get these cases the better it is for both the patient and the operator.

I have no doubt, as before stated, that the first case will be completely cured. It belongs rather to what we may call true conservative surgery. In such cases conservative surgery does not consist in deferring operation, but in exploratory incision, with freeing of adhesions when present, and non-removal of the appendages unless positive evidence of disease of these organs is present. It often requires more courage to return the ovaries than to remove them after the abdomen has been opened.

NOTE.—These cases have all made complete recoveries. Case 1 is relieved in every respect; she has absolutely no pain; the stitches were removed on the seventh day; the incision had united throughout with as near an approach to union by first intention as it is possible to obtain; there was never the least pus, not even a drop of serum from a stitch-hole. She has menstruated since the operation, menstruation being as free from pain as before her abortion.

NEW APPARATUS.

A BIPOLAR STOMACH ELECTRODE (INTRA-GASTRIC).

BY FENTON B. TURCK, M.D.,
OF CHICAGO.

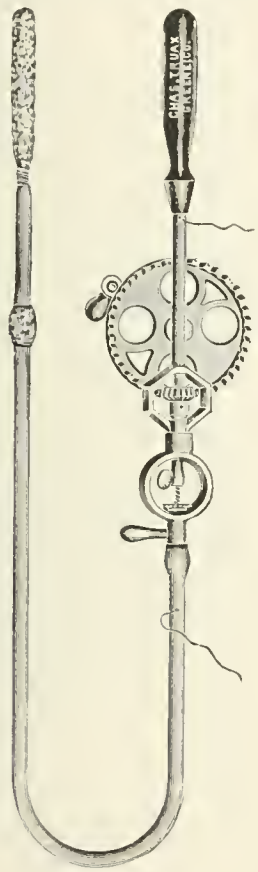
THE gyromele[1] has been used for some time as an electrode within the stomach, and is of special value, as all parts of the stomach can be reached. The other electrope is applied externally. Any value found in the use of intrafaradization or intragalvanization has the additional advantage of the mechanical effects of the gyromele, the massage, and vibratory effect produced by the revolutions of the instrument.

I have devised a bipolar electrode, so that both poles

[1] This was first reported at the International Medical Congress at Rome, 1894; later reported in the *Wiener med. Wochenschrift*, Nos. 1 and 2, 1895: "*Eine neue Methode der Diagnose und Therapie gewisser Magenkrankheiten.*"

can be used within the stomach, with a single gyromele. It is not necessary to use an external electrode upon the abdomen, although it may be used if so desired.

The cable in the gyromele acts as one of the poles; a second wire concealed in the wall of the stomach-tube that ensheaths the gyromele acts as a second pole. At a distance of about two inches from the upper and five inches from the lower distal extremity of the stomach-tube, this is encircled by a narrow metal band. Each band is pierced by the wire that passes within the tube-wall. At the point of entrance of the wire there is a small projection, for the attachment of the wire that leads to the battery. The metal band, which is about five



THE GYROMELE.

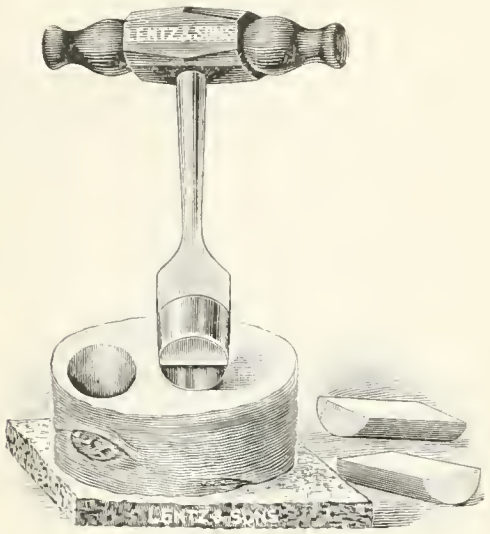
inches from the other end (distal), is covered by a sponge. By drawing the gyromele back and forth, with both poles connected with the battery, all parts of the stomach, from the esophageal opening to the pylorus, can be reached.

A POTATO-CUTTER FOR BACTERIOLOGICAL LABORATORIES.

BY MAZŸCK P. RAVENEL, M.D.,
OF PRINCETON, N. J.,
DIRECTOR OF THE LABORATORY OF HYGIENE, PRINCETON, N. J.

THE method of Bolton for preparing potato as a culture medium for bacteria has been very generally adopted, largely to the exclusion of older methods.

The accompanying cut, which requires no explanation to be understood, illustrates a simple device for facilitating the prepartion of the plugs. A single throw of the cutter



removes a cylinder of the potato, and at the same time divides it into two equal parts, giving a smooth, flat surface for culture. The size of the instrument has been adjusted for the commonly used tube of three-fourths inch inside diameter.

It has been made for me in the most satisfactory manner by Messrs. Chas. Lentz & Sons, of No. 18 North Eleventh street, Philadelphia, Pa., from whom it may be obtained.

MEDICAL PROGRESS.

Repeated Left Hemiplegia in Infancy and Old Age.—LANNOIS and PAULY (*Lyons médical*, 1895, No. 51, p. 562) have reported the case of a man dead of pulmonary tuberculosis at the age of 66 years, who suffered some cerebral disorder at the age of 18 months or two years, followed by left hemiplegia. At the age of 16 years he began to have epileptiform convulsions, which involved primarily the left side, and continued at long intervals until between the ages of 40 and 45. When 55 years old the patient was again seized with left hemiplegia, followed by contractures. Upon post-mortem examination, the right cerebral hemisphere presented a large loss of substance, involving the convolutions adjacent to the fissure of Sylvius, the adjacent convolutions being reduced in size. The cavity formed was occupied by fluid and communicated with the lateral ventricle, but no trace of thrombosis or embolism could be detected. The right cerebral peduncle was much reduced in size, and the opposite anterior pyramid of the medulla was greatly atrophied. In the fresh cord a triangular area of degeneration could be seen involving the left lateral tract, and especially marked in the cervical enlargement.

Pneumococcos Abscess following a Local Lesion in the Course of Pneumonia.—At a recent meeting of the Société de Biologie, ZUBER (*Semaine médicale*, 1896, No. 4, p. 27) reported a case of pneumonia in which an abscess developed at the site of puncture made in injecting caffeine benzoate subcutaneously. The pus evacuated contained pneumococci in pure culture, as shown by direct examination, by culture, and by inoculation in guinea-pigs. This observation illustrates the relation between a point of lower resistance and a constitutional disorder of infectious origin, due to a local lesion with localization of the infective micro-organisms.

Congenital Volvulus.—At a recent meeting of the Société anatomique de Paris, PETIT (*Bull. de la Soc. Anatom. de Paris*, tome ix, Fasc. No. 17, p. 670) reported the case of an infant dead three days after birth in the sequence of symptoms of irremediable intestinal obstruction, the condition of the child forbidding surgical intervention. There had never been an intestinal evacuation, although the anus was patulous. Upon post-mortem examination, a volvulus was found to exist at the junction of the cecum with the ascending colon. The intestine was dragged to the right, passing beneath the cecum, which was provided with a long mesentery. The cecum and the adjacent ileum were twisted twice upon themselves, and continuity with the colon was obliterated. The large intestine was not well developed, while the small intestine was greatly distended and contained a considerable amount of fecal matter.

THERAPEUTIC NOTES.

Rectal Insufflations of Boric Acid for Intestinal Atony.—MERKLE (*Münchener medicin. Wochenschrift*, 1895, No. 52, p. 1209) reports the successful employment of rectal insufflations of boric acid for the relief of the flatulence and constipation dependent upon atony of the bowel. For this purpose he uses a powder-blower, the anointed nozzle of which is introduced into the rectum after thorough separation of the nates. From 30 to 60 grains of boric acid are thus introduced. The nozzle of the insufflator should have a calibre of from .25 to .4 inch and the rubber bulb should be sufficiently large and stout to accomplish its purpose effectively.

Treatment of Grave Anemia with Subcutaneous Injections of Iodine and Iron.—

I. Take of:

Pure iodine	3 grains
Potassium iodide	A sufficient quantity
Distilled water	5 fluid drams.—Mix.

II. Take of:

Iron and ammonium citrate	15 grains
Distilled water	From 2½ to 5 fluid drams.—Mix.

Once or twice daily, fifteen minims of the first solution are injected into the thigh, followed at once by a similar injection of the second.—MENELLA, *Médicine moderne*.

The Treatment of Chilblains.—In the intense form of chilblains without ulceration the affected parts should first be enveloped in aseptic compresses wet with a decoction of walnut leaves (from 1½ drachms to half an ounce of the leaves to a quart of water), and the whole covered with an impermeable dressing.

When the irritation has somewhat subsided the wet dressing may be replaced by an ointment or a powder, as follows:

Boric acid		gr. xv.
Tannic acid		gr. v.
Vaselin		℥ ijss.—M.
Starch, Lycopodium	aa	℥ ijss.
Tannic acid		gr. v.

To maintain the application suitable gloves may be worn. In the mild form of the disorder the decoction of walnut leaves is applied morning and night, and during the day the ointment or powder formulated is used, gloves being worn meanwhile.

When ulceration exists the wound should first be carefully washed with a solution of mercuric chloride 1:1000, and the compresses applied wet with a solution 1:2000. The ulcerated surface may be touched with tincture of iodine or camphorated naphtol, and then covered with aseptic gauze impregnated with borated vaselin or glycerole of starch. When granulations have formed in large numbers the stick of silver nitrate may be applied gently. Should these measures fail, an ointment may be employed, such as that of zinc oxide. If needed constitutionally, cod-liver oil or iron iodide should be administered.

In a prophylactic way those susceptible to chilblains should be advised to be active when exposed to cold and to avoid prolonged exposure and also abrupt change from cold to heat, and *vice versa*. The use of cold lotions throughout the winter may also prove serviceable. At the same time a pill constituted as follows may be taken internally from twice to four times daily:

Quinin. Sulphate, Ergot	aa	gr. ¾
Powdered digitalis-leaves		gr. $\frac{1}{12}$
Extract of Belladonæ		gr. ⅙

—*Press médicale*, 1895, No. 70.

Intoxication from the Topical Application of Pyrogallol.—VOLLMAR (*Deutsche medicin. Wochenschift*, 1896, No. 3, p. 45) has reported the case of a man, 69 years old, who had suffered with psoriasis for twenty years and who was given a 10-per-cent. ointment of pyrogallol for topical application. Two hours after rubbing the ointment into the forearms, there was complaint of intense pain in these parts, with swelling and heat and general restlessness. The little ointment still remaining was at once removed, and cold affusions made. The temperature rose above the normal, and albumin appeared in the urine. In the course of several days these symptoms receded and the case gradually progressed to perfect recovery. There was evidently in this case an idiosyncrasy to pyrogallol, as the amount that could have been absorbed must have been very small.

The Medical News.

A Weekly Journal

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, FEBRUARY 29, 1896.

ANTIVIVISECTION.

In our issue of February 15th we devoted considerable space to a full and complete exposition of the sweeping and indeed almost prohibitory character of the bill now before Congress restricting vivisection in the District of Columbia. And attention was called, in our editorial on the subject, to the probability of this radical movement in Washington being the signal to the so-called humane societies throughout the country for similar local movements in every State in the Union.

This suspicion was evidently well founded; for already a bill of similar import has been introduced into the Legislature of Massachusetts, and it is reported that a like measure is being prepared for the New York Legislature. The Massachusetts Medical Society is showing commendable promptness and vigor in opposing this bill. The society has issued a circular to all its members and to all the prominent medical and scientific men of the State, calling upon them to communicate at once with their respective representatives in the Legislature, urging upon them the absolute necessity of opposing this measure. As the various state societies are liable to be called upon to take similar action at no distant day, it may be well to state that this circular announces that "from the time when Harvey discovered the circulation of the blood 'by frequently looking into many and various living animals' down to the present day, when the discovery of the antitoxin treatment has robbed diphtheria of almost all its terrors, nearly every important advance in medicine has been rendered possible by knowledge acquired through the careful study of the phenomena of life as revealed by what are popularly known as 'vivisections'; that such investigations are at present conducted with every precaution against unnecessary suffering and by men who do not admit for a moment the claim of any society to be actuated by motives more humane than those by which they themselves are guided, and that, as there is no abuse to be corrected, the proposed legislation is totally uncalled for."

There is no doubt that the bills already presented, and others which are doubtless being prepared, if enforced will seriously hamper and may practically abolish biological and medical research. It is therefore the part of wisdom to put forth every effort to strangle them in their birth.

But we, as a profession, may as well recognize the fact that this is a question that will not down. It will rise year after year to hamper and annoy. We would therefore advance the suggestion that the wise and prudent course is, not to await the action of the humane societies, but for each State Medical Society to take the initiative, to instruct its committee on legislation to have a proper bill drawn up, presented, and placed upon the statute-books. This would put a stop to the constant agitation of the subject and preserve by proper restrictions (and it should have restrictions) this valuable and indispensable method of experimental medicine.

A NEW BREED OF "DOGS OF WAR."

No animal has been more abominably and unjustly slandered in proverb and metaphor than the dog. His name has been made a synonym for every evil passion which stirs our bosoms, from the cowardly treachery implied in "Is thy

servant a dog that he should do this thing?" to the savage fury of the classic "dogs of war." And yet these attributes are practically never displayed by the noble brute—except where he has had to associate too much with man, especially in the Orient, where most of these metaphors originated.

At last, however, the "leaden foot" of Justice seems to be coming his way, and he is being brought before the world, in relation to warfare at least, in a rôle more appropriate to his true character.

An ingenious German "cynophile" has been developing the dog's well-known hunting and "ranging" powers as a sort of auxiliary field-hospital corps for finding and carrying aid to the wounded after a battle. According to a recent report in *The Lancet* his experiments gave such promising results that the military authorities recently invited him to make a formal field trial of his canine corps before a committee of experts. The "wounded" were represented by some twenty infantry soldiers, who were scattered behind stumps and rocks, in gullies, and among underbrush over quite a stretch of rough, unbroken country. At the order "Seek wounded" the dogs dashed away, and in a comparatively few minutes discovered and "located" every one of the hidden soldiers. The animals carry under their necks barrel-shaped canteens, each containing water, brandy, and cakes of compressed peptonoids in its compartments. Upon their backs are small packages of surgical dressings, a blanket in cold weather, and in the daytime a number of small flags or pennants with slender pointed stems which the wounded man can set up in the ground by his side, and thus guide the rescue party to him. After dark a small portable electric lamp is attached to the dog's forehead, so that his movements can be followed and his "finds" located. In the intervals of active service the dogs are trained to assist the picket line, acting as water-carriers and as estafets. The committee of experts were so impressed with the value of the dogs that it is intended to have a pack accompany several of the infantry regiments in the field manœuvres next summer. Any one who knows something of the fearful agony often endured from thirst, sunstroke, attacks of insects, and exposure by the wounded in the hours, or even in some cases days, following a battle, will see at once the immense value of such a "corps." In our late war many a poor fellow's life was lost solely from the delay in reaching him; and even in some cases after heavy and scattered fighting in the ravines among the thick underbrush, his remains were not discovered until weeks afterward. The "missing" quota of a regiment is often almost as large as its "killed." All honor and success to the new and only *genuine* "dogs of war," who in the humanity—or shall we say "caninity"?—of their mission have rather the advantage of their comrades of the "higher" species.

THE YEAST PLANT AS A PATHOGENIC ORGANISM.

We have already taken notice in these columns[1] of the introductory work upon the supposed relation of the yeast fungus to the production of certain tumors. Investigation upon the pathogenic properties of these organisms has been unremitting, and we now propose to present another review of the subject, as it promises to occupy a prominent place in the parasitologic discussions of the near future. It is at least safe to predict from the present tendencies that the budding-fungi are destined to receive a large share of the attention which has been so lavishly bestowed upon the supposed protozoan parasite of malignant tumors during the last three years.

The exact botanical position of the yeast plant has not been determined, though it has been known and employed so long in the fermentation industries. The morphology of many species of the yeast family is so inconstant that several botanists have looked upon the organism as a developmental stage of one or another of the filamentous fungi. Thus Juler and Jörgensen have very recently attempted to prove by their studies that the budding yeast cells represent but one stage in the development of true molds. When it is remembered that certain filamentous fungi like *Achorion Schoenlinii*, and *Trichophyton tonsurans* are well known human parasites, and that some molds like *spergillus* have been found to flourish in a parasitic relationship in man and other animals, both naturally and experimentally,

[1] Editorial, April 6, 1895, pp. 383–384.

then it does not seem improbable that the yeast plant, which is so much better adapted morphologically for a parasitic existence, should find a favorable soil for growth in the animal body.

The earlier experimental work upon the pathogenesis of the yeast organism was done by Neumayer, and Raum. Neumayer found that these plantlets possessed wonderful resistance against the digestive juices of animals, as living yeast-cells could be regularly recovered in the stools after the ingestion of considerable quantities of yeast. The administration of large quantities of this material by the mouth led to a gastro-enteric catarrh, doubtless on account of the irritative effects of the fermentative products resulting from the metabolic activities of the living yeast-cells. Raum used pure cultures of various species of *Saccharomyces* and uniformly produced death in rabbits by intravascular injections. Examinations of the organs of these animals showed that the fungal cells accumulated only in the lungs, where they thrombosed the blood-vessels. In only one case, in which a rabbit died two or three weeks after an intravenous injection, could Raum recover the organisms from the subcutaneous tissue, where a small caseous tumor had formed.

In 1894 Busse claimed to have isolated a species of yeast in pure culture from a sarcomatous-like subperiosteal neoplasm on the tibia of a woman. Inoculations with the tumor tissue and with pure cultures of the yeast fungi into rabbits and dogs were successful in so far that they showed the parasites to possess pathogenic properties; but no true tumors were produced. The striking resemblance of the vegetable cells in the affected tissues led Busse to compare them with the cancer inoculations, especially those described by Darier and Wickham.

Sanfelice followed with a record of his experiments with artificial cultures of a pathogenic variety of the yeast fungi obtained from fermenting fruit juice. The remarkable feature about this work lies in the regularity with which the experimenter succeeded in producing *neoplastic formations* in the lymphatic glands and certain visceral organs of his inoculated animals. Guinea-pigs were largely employed in this work, and after an interval of four to six weeks following an injection they died, showing numerous tumor-like foci from which the fungi could be recovered both in culture, and in various microscopic preparations. In his several published reports Sanfelice has always dwelt upon the resemblance of the yeast-cells in the infected tissue to the cancer parasites of almost all the workers who have in the past three or four years described these objects.

Simultaneously with these researches, Colpe found a pathogenic budding-fungus in a case of chronic cervical endometritis which he believed to be the etiologic factor in the affection.

Fermi and Aruch of Rome obtained a yeast culture with marked pathogenic properties from the lympathic tissue of horses affected with a peculiar form of infectious lymphangitis. From the purely histological side, Ajevoli and Pianese have attempted to identify certain so-called tumor parasites with yeast cells; and Roncali gives an elaborate description and a highly colored lithographic picture of certain round or oval bodies found in sections of an adeno-carcinoma of the human ovary, wherein he insists upon their yeast-like character, and their identity with similar objects previously looked upon as the protozoan parasites of malignant tumors. Corselli and Frisco present a preliminary communication upon their studies of pathogenic budding-fungi, and they report a case of sarcoma of the mesenteric glands in a woman, accompanied by chylous ascites in which pure cultures of yeast were obtained from the tumor tissue and from the ascitic fluid. These cultures were pathogenic in rabbits, dogs, and guinea-pigs, and in the latter animals tumors were produced very like those described by Sanfelice, and the animals died in twenty or thirty days.

As tempering, somewhat, these almost inconceivable results, obtained mostly by Italian investigators, comes the painstaking experimental study by Lydia Rabinowitch, made under the directions of Professor Koch. This investigator made inoculation experiments with about fifty different species of yeast. Out of these she found seven which possessed pathogenic activity when injected subcutaneously into mice and rabbits, though none of these cultures was pathogenic in guinea-pigs. The animals died

between the first and fourteenth day following the inoculation; vast numbers of yeast cells could be found in all the organs on appropriate treatment; and the pure cultures could be recovered from these organs. For the most part the fungi were disposed in the tissue spaces, though occasionally an intra-cellular parasite could be found. In all of these experiments, however, no chronic illness with the formation of neoplasms, such as noted above, could be induced.

From this very brief summary of the work done for the most part during the past year upon the yeast plant as a disease-producing organism, it seems to us certain that a new and very promising field of mycologic research has been opened—one which promises to materially extend our knowledge of certain infectious diseases, and one which may prove of vast importance in solving the mystery which still surrounds the etiology of malignant neoplasms.

We can at least feel assured, with the illustration afforded by the sporozoan theory of tumors, that a flood of literature by a host of investigators working in the new field will be poured upon us during the next year or two. Pathology has its fashions, and every one wants to be in the fashion.

ECHOES AND NEWS.

There have been no startling discoveries in the experiments with the X ray during the past week. Observations have been continued along the lines already suggested, and with marked success. By the use of a bell-jar, placed over the Crookes tube, the time of exposure has been reduced to seconds, making the pictures practically instantaneous. One experimenter announces that he has increased greatly the penetrating power of the ray and has thus secured shadow pictures through a block eight inches in thickness. Practical application has been continued in locating bullets, buckshot, needles, and other foreign bodies in the flesh. But no one has succeeded in destroying bacilli in their local habitat in the human body.

A bill has passed the Legislature of Virginia authorizing the appointment of female physicians for the female wards of the State insane-asylums.

The Illinois Medical College, of Chicago, has, through the advice of the more conservative members of its faculty, abandoned the proposed hypnotic clinic. The matter was receiving such sensational prominence that this course became necessary.

Haverhill, Mass., is suffering from an epidemic of diphtheria, and the authorities have been requested to formally order the schools closed. Of sixteen cases reported all have been traced to one school building.

Through a misunderstanding that has arisen between the faculty and the Board of Trustees of the New York College of Dentistry, the legal existence of this prosperous institution of learning is threatened.

A civil-service examination is staring the city physicians of Rochester, N. Y., in the face, since the Mayor refuses to remunerate them unless supplied with certificates of the Civil-service Examining Board.

Ohio has just acquitted herself in a most commendable way, by passing, without amendment, and with only one dissenting vote, a law regulating the practice of medicine. The profession of that State are to be congratulated upon this unprecedented success as a result of almost a quarter of a century of patient effort.

The annual convention of the World's Congress of Medico-climatology, held at San Antonio, Tex., formally adjourned on February 22. Papers were read by Dr. A. F. McKay, of Chicago, and Dr. A. M. Johnston, of San Antonio. A committee composed of Drs. Paul Paguin, of St. Louis; C. D. Hurt, of Atlanta; G. M. J. Bliem, of San Antonio; J. A. May, of New Holland, O.; and J. T. Acomb, of Pennsylvania, was appointed to report at the next convention on the advisability of petitioning Congress to establish sanitariums in different parts of the country for scientific study of consumption. Atlanta, Ga., was chosen as the next place of meeting.

The Camden County Medical Society, of New Jersey, has recently celebrated with appropriate ceremonies the semi-centennial of its organization. Among other proceedings of interest, busts of two of its founders and charter members, Richard M. Cooper, M.D., and Othniel H. Taylor, M.D., were presented to the Society.

The Woman's Health Protective Association of Philadelphia are adding laurels to the reputation of their association by their activity and success in procuring improved service from the street-cleaning department of that city.

Dr. Alexander T. Hunter died at his home in Spuyten Duyvil, N. Y., Feb. 14, 1896. He was born at Conesville, N. Y., in 1839, and was graduated from the New York University Medical College in 1863. In 1890 he was elected president of the New York County Medical Society. He was the first president to succeed himself since the organization, in 1807.

The old and well-known College of Medicine of Ohio, situated at Cincinnati, has become the Medical Department of the University of Cincinnati, and hereafter will be known by the double title of "The Medical Department of the University of Cincinnati" and "The Medical College of Ohio."

ON February 4, 1896, the Meharry Medical College of Tennessee, the principal medical college for the negro of the South, if not of the United States, held its commencement exercises, graduating eleven candidates. As a rule, the alumni of this institution are doing commendable work among their own race in the Southern States, where they command general respect.

DR. DONALDSON SMITH, of Philadelphia, returned last week from central Africa, where he has discovered several curious tribes of people, concerning which he will make a scientific report in due time.

DR. JOSEPH JONES, one of the most prominent members of the medical profession of this continent, died at his home in New Orleans on the 17th instant. He was a graduate of the University of Pennsylvania in 1855, and almost immediately thereafter was made professor of chemistry at the Medical College of Savannah, Ga., and filled this and associate chairs in the University of Georgia, the University of Nashville, and Tulane University at New Orleans in rapid succession. Since 1868 he has been identified with the latter, giving liberally of his time and remarkable talents to the service of his city and state. To him more than to all others is due the improvement of the sanitary condition, not of New Orleans alone, but of the whole Valley of the Mississippi. His ability as a scientist and historian was perhaps more widely recognized abroad than in this country.

DR. WILLIAM THOMSON, professor of ophthalmology at the Jefferson Medical College, Philadelphia, has been elected to succeed the late Dr. H. Earnest Goodman as attending surgeon to the Wills Eye Hospital.

ST. MARY'S Free Hospital for Children of New York, has purchased near Norwalk, Conn., thirty acres of land, and will erect on the property commodious hospital buildings. The property will be known as the Summer Home of St. Mary's Free Hospital for Children of New York.

MANY cases of typhoid fever have developed within the past few weeks in the Greenville district of Jersey City. The source of the contagion has been discovered in the wells from which the drinking-water was taken.

THE second annual meeting and dinner of the Brooklyn Alumni Association of the Bellevue Hospital Medical College was held at the Lincoln Club, Brooklyn, on Monday night, February 17, 1896. The following officers were elected for the coming year: Dr. George R. Fowler, president; Dr. George McNaughton, vice-president; Dr. L. W. Pearson, secretary; Dr. W. Waterworth, treasurer; Drs. R. M. Wyckoff, A. Pell, and J. Scott Wood, members of the Board of Managers. Toasts were responded to by Prof. A. A. Smith, M.D., of Bellevue College, Dr. W. H. Katzenbach, ex-president of New York Alumni Association, Drs. G. A. Evans, G. R. Fowler, and others.

DENNIS' AMERICAN SYSTEM OF SURGERY.—Scant attention is due to an anonymous paragraph which recently appeared in an English periodical, charging plagiarism against the new System of Surgery by American authors, the concluding volume of which will shortly appear. The charge is devoid of details and the name of the accuser is withheld, so that more than a general and absolute denial of the truth of the statement is alone possible. American surgeons, especially those of the eminence of the contributors to the American System of Surgery, have neither need nor desire to borrow ideas or language from their English *confrères*. The derivation of illustrations from various sources is customary on both sides of the Atlantic and is a practice common to nearly all medical works, without regard to country. The essence of the charge seems to lurk in the fear that the American System of Surgery would prove too successful a rival to native works, and hence the attempt on the part of English publishers to protect their market against competition. What higher compliment could be paid to the excellence of this latest production of American surgeons—the confession of fear to submit to rivalry?

A MOVEMENT is again on foot looking toward building, or making provision for a hospital for contagious diseases in the city of Brooklyn, to which persons able to pay for attention and care could be taken,

RESOLUTIONS ON THE DEATH OF THE LATE DR. JOHN H. RIPLEY, OF NEW YORK.

AT a special meeting of the Medical Board of St. Francis Hospital, of New York city, held February 18, 1896, the following resolutions were adopted:

WHEREAS, It becomes our painful duty to announce the death of Dr. John Howard Ripley, attending physician to the St. Francis Hospital, New York, and late president of its medical board; therefore, be it

Resolved, That the Medical Board desires to place on record its due appreciation of his long and valuable services to this institution, faithfully and cheerfully rendered for nearly a quarter of a century.

Resolved, That from his first connection with this hospital he was an ever-willing servant for its best interests, an ardent promoter of its highest aims, and an active participant in all its charitable benefactions.

Resolved, That his untiring zeal in the performance of his arduous and responsible duties, his wisely conservative judgment, his painstaking accuracy of observation, and his ever available and profound knowledge of clinical phenomena were qualities that command the highest respect of his associates and stimulate the emulation of all who share the results of his unselfish labors.

Resolved, That the remembrance of his manly disposition, his frank manner, his energetic spirit and scholarly attainments will ever serve as a cherished lesson from the well-ordered life of a dutiful worker, an indefatigable investigator, and a model physician.

GEORGE F. SHRADY, M.D., President.
G. M. EDEBOHLS, M.D., Secretary.

CORRESPONDENCE.

COLD BATHS A HEART STIMULANT.

1605 Walnut Street,
Philadelphia, February 22, 1896.

Editor of The Medical News.

Dear Sir: In the last issue of the News (p. 223) I have been made to say that my greatest contra-indication to the cold bath is a feeble heart. This is incorrect. I stated that an excessively weak heart should be regarded as *one* of the contra-indications to the rigid cold-bath treatment. If for no other reason, it is inadvisable under the circumstances, because of the fact that the patient exerts himself or even struggles against the unpleasant effects of the extreme cold. No one is more fully convinced that the external use of cold is a potent stimulant to the nerve centres, including the cardiac, than myself.

Sincerely yours,
J. M. Anders.

OBSERVATIONS ON THE X RAY.

By Mr. T. C. McLennan, B.A., and Mr. C. H. C. Wright, B.App.Sc., and T. Keele, B.App.Sc., of Toronto, Canada.

[Special correspondence to the Medical News.]

These observers, after experimenting for some time and obtaining clear negatives from long exposures to the X rays, succeeded in reducing the time necessary for a distinct image, through five folds of black paper, to one second. These results were obtained by covering the Crookes tube with a glass bell-jar. While these gentlemen do not wish to be understood as claiming that this conclusively proves reflection of the X rays, this explanation for the results obtained appears to be the only reasonable one. They found that without the bell-jar a piece of plate-glass placed between the tube and the sensitized plate, and at a distance of 10 cm. from each, acted as an opaque screen; but when the bell-jar covered this arrangement the action on the plate was very distinct immediately below the glass screen. The rays are in this case probably reflected by the bell-jar around and under the glass screen. These observers succeeded also, by this method of concentrating the rays, in locating the point of a needle between the second and third metatarsals in a patient's foot so definitely that the surgeon was enabled by a single incision to remove it. They are now working on the subject of the reflection and refraction of the rays, and they will make a report of their progress to the Canadian Institute at its first meeting in March.

CONTINUED EXPERIMENTS WITH THE X RAY.

[Montreal letter from our special correspondent.]

Montreal, Canada, Feb. 17, 1896.

Professor Cox, of the science department of McGill University, continues to experiment with the X rays. He is somewhat hampered by the difficulty of obtaining Crookes or Geisler tubes. Several of those in stock which were remarkably fine ones were destroyed by using too powerful currents, the connections at the poles having melted out. Some experiments have been made with a view to employing induction and thus doing away with the metallic connections, but they have not yet reached a satisfactory stage. The Rumkorff coil used by Professor Cox is an old one, but apparently a very good one, as it gives sparks ten inches in length. A few days ago a medical student who had been suffering for some years from an injury of the elbow joint submitted his arm to the X ray, when a clear picture of the injury was seen. With this positive diagnosis it is probable that, as in the case of the young man with the bullet in his leg, the medical student will shortly submit to operation for the cure of his injury. One of Professor Cox's assistants yesterday obtained a very fine photograph of an athlete's hand. Each bone and joint shows in a remarkably distinct manner, those in the palm of the hand and wrist being as clearly defined as those of the fingers. The flesh shadow which surrounded the bones in the previous photos is hardly visible in the present picture.

STREET EXPECTORATION.

Denver, Col., Feb. 17, 1896.

To the Editor of The Medical News:

Sir:—I often read with considerable indignation some of the nonsense written and published, after immature consideration, in regard to Colorado.

In your issue bearing date of February 15th, one of your contributors writes that "a person(?) recently returned from Colorado said 'the streets are *fairly slippery* from the expectorations of consumptives who are there for their health.'" Of course the assertion is not your contributor's own, but he gives publicity to it as though he vouched for its truthfulness, and thus another silly lie is started upon a long and malicious career, bearing a certificate of character from the writer.

Medical writers ought to given more careful investigation to such bold statements before accepting and reiterating them.

Colorado physicians keenly realize that our streets are not yet as clean as those of New Jerusalem, nor can they be so until education and refinement have more thoroughly leavened the mass of our population. But I know that our streets compare very favorably, as to freedom from expectoration, with those of New York, Philadelphia, Chicago, Pittsburg, St. Louis, and Detroit, perhaps even with those of Syracuse.

In our street-cars any one who cares to look may see this legend:

Bureau of Health Notice:
Do not spit on the floor,
Because Consumption is Communicated by the Expectoration.

In hotels, lodging-houses, places of public resort, and in many stores similar placards with explanatory, succinct paragraphs are to be found.

Thousands of pamphlets and circulars in regard to the prevention of tuberculosis are distributed to patients by the Bureau of Health, and apartments that have been occupied by consumptives are fumigated by the authorities.

In a word, there exists in Colorado, probably to a greater extent than elsewhere in America, proper offi-

cial recognition of the contagiousness of tuberculosis; and that official action is but the expression of a widespread, general, and intelligent realization by our community (30 per cent. of them consumptives) of the necessity for such care. Very respectfully,

Wm. P. Munn, Health Commissioner.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Monthly Meeting, February 17, 1896.

Joseph E. Janvrin, M.D., President.

THE ULTIMATE RESULTS, IN MY OWN EXPERIENCE, OF VAGINAL HYSTERECTOMY FOR CANCER ORIGINATING IN THE CERVIX UTERI.

Dr. Janvrin made some introductory remarks on assuming the presidency of the Association, and then read a paper with the above title. (See page 225.)

DISCUSSION.

Dr. William T. Lusk said that he believed that he was the skeptic at the meeting of the Obstetrical Society referred to in the paper. At that time he had asked whether any one had ever seen a case of the kind mentioned by the president, Dr. Janvrin, in which there was not a speedy relapse after operation. At all events, there had always been a speedy recurrence in his own cases, and he thought that this was the experience of most operators. He had never been able to gather any very definite information in regard to this subject. When he was in Europe last summer he had spoken to Jacobs in regard to the matter, and the latter had given a very vague reply, but at the same time acknowledged that the results of his cases of vaginal hysterectomy were very disappointing. In London, Knowsley Thornton had spoken in very much the same strain, and the same was true of other prominent gynecologists. On account of the unsatisfactory results that had been met with, Dr. Lusk said that he, as well as a number of other operators, had returned to the old Shroeder method.

In view of these facts, the showing made of the cases presented this evening by Dr. Janvrin was all the more remarkable, and he wished to heartily congratulate the president on the very gratifying measure of success that he had attained. Certainly the operation of vaginal hysterectomy as a procedure was in every way preferable to the Shroeder operation. As performed at the present day, it was attended with the smallest possible amount of risk, and it was much easier to do than the Shroeder operation. As a result of the brilliant success reported here to-night he would take hold of the subject with new interest and zest, and he hoped that in the future he would be able to report results less gloomy than those he had hitherto met with.

Dr. Herman J. Boldt thought that in the future the results of this operation would be much better than they had been in the past. It was very important that the cases operated on should be selected with great care and that the operation should be performed at as early a stage of the disease as possible. Much also depended, he believed, on the technique. Until recently there had been much to condemn in the manner in which the operation was done, but of late years advances had been made. Especially was this true in regard to the use of the cautery, as advocated by Dr. Byrne in this country, as well as some European authorities. When this was more generally adopted, he believed that the results met with would be appreciably better. One great cause of recurrence was that, on account of the condition of the lymphatics, the surgeon was apt to infect some of the sound tissues during the operation, and by the use of the cautery this could be avoided. On the whole, however, he had to confess that up to the present time he had been obliged, by the results obtained, to take very much the same view of the subject that Dr. Lusk did. In conclusion, Dr. Boldt congratulated Dr. Janvrin on his skill in avoiding injuries to the ureters during his operations, as this accident was not infrequently met with by other operators. In connection with his remarks he presented a uterus, in the removal of which the Pacquelin cautery had been used.

Dr. George T. Harrison regretted that he had not been able to get to the meeting in time to hear the president's paper. He said that of all the triumphs of modern gynecology this was the grandest achievement—to be able to remove the entire uterus when the seat of carcinomatous infiltration, and thus save the lives of many women who formerly would have been irrevocably doomed. The statistics which he had gathered on the subject showed that about 17 per cent. of all those operated on were permanently cured. But, Why, he asked, should the other 83 per cent. be allowed to perish? He believed that as soon as it was possible to make a diagnosis earlier in this class of cases, we should have much better results to show. This was a matter of extreme importance, because cancer, we have every reason to believe, was at first a purely local disease.

One great difficulty in the way of improvement in this respect was that women do not appreciate the great significance and importance of atypical uterine hemorrhages occurring, especially in middle life. He therefore thought that every family practitioner should make it a matter of conscience to call a competent gynecologist in all cases of atypical hemorrhage in this class of patients. If, in the majority of instances, an early diagnosis of cancer could be made and the operation be performed as soon as possible thereafter, the statistics would undoubtedly show a very much larger percentage of cures. It could be laid down as a rule that when five years had elapsed after the operation without any signs of recurrence the patient might be regarded as positively and permanently cured. The mortality from the operation itself was a little over 9 per cent.

Dr. A. Palmer Dudley, who was present by invitation, said that he did not think he could add much of value to the discussion. Still, there were some points to which it might be well to call attention. In considering the liability to recurrence in any given case, there were

three prominent circumstances to be taken into consideration, viz.: First, the age of the patient; second, the extent of the disease; and, third, the manner in which the latter was attacked. A woman who was in active menstrual life was much more apt to have a relapse than one who had passed the climacteric. Also, if a considerable portion of the vagina or other surrounding parts had become involved, there was a much greater chance of recurrence than in cases of a simpler character.

Dr. Dudley spoke for some time in regard to the technique of the operation, and said that it was still an open question whether the open method was preferable or not. Personally he believed it was better to secure primary union whenever this was possible, rather than healing by granulation, for the reason that in the case of the former there was less liability of return, and he had frequently observed that recurrence was apt to begin in the seat of the cicatrices left by granulating wounds. There was one advantage, however, he thought, in the use of the clamp, viz., that by this means portions of the broad ligament could be crushed at a higher point than could be reached by ligatures, and without the danger of doing injury to the ureters.

As to the general importance of an early diagnosis, he fully agreed with Dr. Harrison, but he thought it necessary to remember that hemorrhage is not an *early* symptom. Pain, discharge, feelings of discomfort, were the things that should arouse the suspicion of cancer before any hemorrhage appeared, and he was of the opinion that every general practitioner should be able to make an early diagnosis of the disease himself. The time would come, he had no doubt, when this would really be the case, and then we should be able to show much better results than at present. In reviewing his own cases, he had found that the average time of recurrence was from eighteen months to two years, and he thought this was about the average of operators in general.

Dr. Janvrin, in closing the discussion, said that he agreed with Dr. Boldt as to the importance of carefully selecting the cases for operation, and with Dr. Harrison that cancer was primarily, and for a considerable length of time, a purely local disease. While in cases seen early vaginal hysterectomy offered a very excellent chance of permanent cure, in those in which there was a regular cauliflower excrescence, with extensive implication of the vagina or other parts, such an operation was, in his opinion, certainly unjustifiable. In these advanced cases it was sometimes necessary, however, to perform a modified operation (palliative and not radical) for the relief of hemorrhage and pain, and in this way the patient could be often spared much suffering in her declining days.

Personally he (Dr. Janvrin) had never directly closed the peritoneal surfaces, but it was his practice to draw the broad ligament stumps down into the pelvic cavity, on a level with the upper part of the vagina and then apply the gauze tampon, thus shutting off the peritoneal cavity from all raw surfaces below. If he found much difficulty in applying ligatures to the broad ligaments, he frequently combined the use of the hemostatic forceps with the ligatures, sometimes using a half-dozen, and thus hastening the operative work. The forceps were usually removed at from thirty-six to forty-eight hours. In every case reported in the paper the specimen had been examined by a competent pathologist and pronounced malignant, and in several instances a portion of the cervix had been removed prior to the hysterectomy and examined and pronounced malignant. In conclusion, he said that he felt exceedingly gratified that the subject had been so fully and thoroughly discussed by the gentlemen who had had large experience in operative work in these cases.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, February 20, 1896.

Joseph D. Bryant, M.D., President.

The Recent Progress of Treatment in Affections of the Upper Respiratory Tract.

(*a*) *Nose and Accessory Sinuses.*—Dr. F. H. Bosworth opened the general consideration of the above theme, by a paper on the nose and accessory sinuses. He said that among the prominent factors that had been responsible for the progress in this department of medicine during the past fifteen years was the discovery of the local anesthetic properties of cocaine, by Carl Koller. Aside from its anesthetic action, this agent had contributted much to larynology and rhinology by its property of squeezing the blood out of vascular tissues, and so facilitating both diagnosis and treatment. In 1885 had appeared what he considered to be the first paper in which was presented the true physiology of the nasal passages. He had contended that the function of the turbinated bodies was to pour out serum, which was taken up again by the inspired air. A proper appreciation of the important function of the nasal passages made it evident that the important indication for treatment was to restore, or maintain the normal respiratory function of these passages. He did not think the nasal septum had any particular function, and consequently if it encroached upon the lumen of the passages it was proper to cut it away freely. It was now known that a purulent discharge indicated an empyema of one of the accessory sinuses. Ethmoid disease he has found to be frequently accompanied by diseases of the antrum. Both diagnosis and treatment were more definite than formerly.

Dr. M. J. Asch said that in the enthusiasm over the value of cocaine it should not be forgotten that the abuse of this drug had often led to the development of a drug habit almost as baneful as the alcohol or morphine habit. Another danger from cocaine arose from this very important property of temporarily depleting the tissues of blood, for operations done under cocaine anesthesia were sometimes followed by secondary hemorrhage. Although puncture of the inferior meatus in disease of the maxillary sinus had been recommended as a simple method of treatment, he had found that such was not the case, and that owing sometimes to the peculiar conformation of the sinus a puncture through this meatus entirely failed to reach the sinus.

Dr. R. C. Miles said that he could hardly conceive of nasal surgery being carried on intelligently without the

use of cocaine. The nasal septum, in his opinion, was not as useless as Dr. Bosworth seemed to believe; its numerous glands should be enough to refute such a statement. In the treatment of polypoid degeneration of the frontal sinus, he had obtained good results from curetting.

DR. J. W. GLEITSMANN said that he had also met with difficulty in puncturing the antrum of Highmore from the lower meatus with Schmidt's instrument, until Schmidt had called his attention to the fact that the point of puncture should be about three-fourths of an inch posterior; since then he had frequently done it with good result.

DR. BOSWORTH said that he had never met with a case of cocaine habit that had seemed to him much more serious than the chewing-gum habit. In many of the so-called cases of cocaine habit alcohol or morphine was an important factor.

(*b*) *The Pharynx.*—DR. J. E. NEWCOMB read a paper on this division of the subject. Speaking of the best general anesthetic to use for very short operations, he said that there was much evidence to show that the bromide of ethyl was particularly well adapted for this purpose. With this agent the period of excitement is very transient, vomiting is rare, the vapor does not irritate, and there is no tendency to cardiac disturbance or cerebral anemia. Its disadvantages are that it produces hypersecretion, and if too long inhaled may produce muscular contractions. In the production of local anesthesia, it had been found that the effect of cocaine could be prolonged and intensified by mixing it with antipyrine; indeed the hypodermic injection of a 50-per-cent. solution of antipyrine alone had been found sufficient to relieve dysphagia for twelve hours at a time. In the treatment of naso-pharyngeal tumors, the speaker said, the hot snare was not now so commonly resorted to. Electrolysis had yielded good results, but statistics on this point were far from accurate. Metallic electrolysis—*i.e.*, the use of a certain metal for the positive electrode, by which this metal was dissolved by the current and deposited deeply in the tissues—promised good results. When this method was employed, it was customary not to use cocaine, as the operator desired to be guided somewhat by the sensations of the patient. Mycosis was a condition, often dependent upon a rheumatic or gouty diathesis, which demanded the use of antiseptic solutions, or, better still, the application of the electro-cautery.

Enlarged tonsils in persons under sixteen years should be removed by some form of guillotine, but in older persons, or where the tonsils were fibrous, and liable to bleed, igni-puncture was more appropriate. For adults, if the shape of the tonsil permitted, he favored the use of the hot snare. Where the tonsils were acutely inflamed, one of the best internal remedies, according to his experience, was salol, although at the outset a tonsillar inflammation might frequently be checked by the local application of guaiacol. Where suppuration seemed inevitable, one should not wait for the abscess to point, but should resort to early incision.

DR. GLEITSMANN said that he had found that bromide of ethyl possessed the advantages claimed for it in the paper, but it had seemed to him that its anesthetic action was rather too transient for most purposes. He could speak from personal experience of the satisfactory action of a 50-per-cent. solution of antipyrine, hypodermically administered, in certain obscure neuralgic conditions.

(*c*) *Larynx and Trachea.*—DR. D. BRYSON DELAVAN discussed this portion of the subject. He said that intubation was growing in favor as a mode of treating chronic stenosis of the larynx. A new method of treating benign neoplasms of the larynx, and one that bade fair to be exceedingly useful, was the frequent spraying with absolute alcohol. Two cases in his own practice had been completely cured by this simple treatment. In the treatment of malignant disease of the larynx, three recent operations were worthy of consideration. They were: (1) Thyrotomy; (2) complete laryngectomy; and (3) laryngectomy, with removal of involved glands. Dr. J. Solis Cohen's plan of attaching the divided end of the trachea to the edges of the cervical wound was a good one, for it decidedly diminished the chance of inspiration pneumonia, and in several cases so treated there had been quite good phonation. Tracheotomy should precede thyrotomy by several days, and in dividing the cartilage it is well to interrupt the continuity of the incision and form a sort of angular recess, so as to assist in keeping the cartilaginous margins in coaptation after the operation. One of the best methods yet proposed for the treatment of tubercular laryngitis was that brought forward recently by Dr. W. F. Chappell, viz., submucous injections of creosote into the diseased tissue.

DR. ROBERT ABBÉ said that he wished to call attention most emphatically to the fact that operations on the larynx for malignant disease should only be undertaken by surgeons of skill and experience. The only hope of accomplishing much in this class of cases lay in a very radical operation—the removal not only of the neoplasm and the parts evidently infiltrated by it, but also of the neighboring glands. If this were not done, it would be found that owing to the abundant lymphatic supply to the larynx, recurrence would be exceedingly rapid. Feeding after laryngectomy could be accomplished without difficulty by the use of a catheter introduced through the nose. To prevent the passage of blood during the operation into the trachea, he had used a number of small sponges, with strings attached, packed around the common tracheal tube. This had proved much more satisfactory than any of the special devices for this purpose. His experience with laryngeal papillomata had impressed him very strongly with their remarkable tendency to recur after the most thorough excision and cauterization of the parts. He hoped therefore that the new method of treating these benign but very troublesome growths, by spraying with absolute alcohol, would turn out to be all that was claimed for it.

DR. W. F. CHAPPELL said that while the physician must expect to meet with many disappointments in the employment of any method for the relief of laryngeal tuberculosis, recent acquisitions to our knowledge of this subject certainly enabled us to hold out a better prospect of relief than we were formerly enabled to do. Allusion

has been made to his method of treating this condition by injections of creosote. Some of the cases he had treated in this way had exhibited a remarkable degree of benefit, and almost all of them had improved since he had first reported upon them, in March, 1895. Rest was an exceedingly important part of any plan of treating tuberculosis, whether of the larynx or of the lungs.

REVIEWS.

Twentieth-century Practice of Medicine: An International Encyclopedia of Modern Medical Science, by Leading Authorities of Europe and America. Edited by Thomas L. Steadman, M.D., New York city. In twenty volumes. Vol. VI, Diseases of the Respiratory Organs. New York: William Wood & Co., 1896.

Volume VI of this work, just out and now before us, consists of eight parts by different authors, all of which relate to or have some bearing upon the respiratory organs. The first is by Prosser James, of London, on "Diseases of the Nose." Not only does the interior of that organ receive due attention, but considerable space is devoted to external diseases, including acne, lupus, epithelioma, and even injuries. By placing so much information before the reader in a practical way, the volume is not over large and bulky, though the type is of ample size and clear.

The second part is by Dr. Jonathan Wright, of Brooklyn, N. Y., on "Diseases of the Accessory Sinuses of the Nose," by which he refers to the maxillary (antrum), frontal, ethmoidal, and sphenoidal sinuses. In order to shorten the article the author has, and wisely too, we think, inserted drawings made from specimens rather than occupy time and space by exhaustive anatomical descriptions.

E. J. Moore, M.D., of Bordeaux, contributes the third and fifth parts, the former being on the "Naso-pharynx and Pharynx," and the latter on the "Diseases of the Tonsils." Between these two parts comes a short but practical article on "Diseases of the Ear," by Dr. Albert H. Buck, of New York, though one would hardly expect to find such a subject in a work on diseases of the organs of respiration. Regarding diphtheria-antitoxin, the author of diseases of the tonsils very properly refers to the occasional inconveniences arising from its use as well as the benefits claimed, and states that the method is still being developed.

The sixth part is by Dr. Francke H. Bosworth, of New York, on "Diseases of the Larynx." The reference to the anatomy of the larynx, though brief, is amply sufficient for practical purposes. In fact, throughout the book the author appears to have had in mind what the work professes to be, that is to say, twentieth-century practice. Comparisons are said to be odious, but if we had to pass judgment we should express the opinion that Dr. Bosworth's article is one of the best in the book.

The seventh part is on the "Diseases of the Trachea and Bronchial Tubes," by Sir Thomas Grainger Stewart, of Edinburgh, assisted by Dr. George Alexander Gibson. One need only to read the article on "Asthma" to see how eminently practical and modern are the views held by the authors. In fact, the name of Grainger Stewart alone is guaranty of the soundness of this part.

The eighth and last part in this volume is on "Diseases of the Lungs" (exclusive of croupous pneumonia and tuberculosis), by Winslow Anderson, M.D., of San Francisco, Cal. Pneumonia and tuberculosis will doubtless appear in the next volume, being omitted here on account of the increased size of the book that would be required. Dr. Anderson's article appears to be all that could be required of the author.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from January 14, 1896, to February 3, 1896.

First Lieutenant Harry M. Hallock, Assistant Surgeon, is relieved from duty at Fort Bayard, New Mexico, and ordered to Fort Logan, Colorado, for duty at that post.

Captain Benjamin L. Ten Eyck, Assistant Surgeon, now at Columbus Barracks, Ohio, is ordered to Fort Niobrara, Neb., for temporary duty.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending January 25, 1896.

January 21.—Surgeon C. A. Siegfried, detached from the "Texas" and ordered to the "Columbia." Surgeon W. G. Farwell, detached from the "Columbia" and placed on waiting orders. Passed Assistant Surgeon J. A. Guthrie, detached from the "Texas" and ordered to the "Katahdin."

For Week Ending February 1, 1896.

January 27.—Assistant Surgeon A. B. Pusey, detached from the "Cincinnati" and ordered to the "Vermont." Assistant Surgeon G. C. Hubbard, detached from the "Vermont" and ordered to the "Cincinnati."

January 28.—Assistant Surgeon C. M. De Valin, ordered to the naval hospital, Philadelphia.

January 30.—Surgeon J. M. Steele, detached from the Torpedo Station and ordered to special duty on the "Independence." Surgeon M. H. Simons, detached from special duty at Portsmouth, N. H., and ordered to the Torpedo Station.

January 31.—Medical Inspector G. F. Windslow, detached from the "Philadelphia" and granted three months' leave. Surgeon J. A. Hawke, detached from the "Baltimore" and ordered to the "Philadelphia," as fleet surgeon of the Pacific Station. Assistant Surgeon A. Farenholt, detached from the "Baltimore" and ordered to the "Monterey."

Official List of the Changes of Station and Duties of Medical Officers of the U. S. Marine Hospital Service for the Month Ending January 31, 1896.

Stoner, G. W., Surgeon. Granted leave of absence for thirty days with pay, and not to exceed sixty days without pay, January 15, 1896.

Pettus, W. J., Passed Assistant Surgeon. Granted leave of absence for thirty days, January 2, 1896.

Magruder, G. M., Passed Assistant Surgeon. Leave of absence extended nine days, January 2, 1896.

Goodwin, H. T., Passed Assistant Surgeon. Granted leave of absence for sixty days, January 4, 1896.

Smith, A. C., Passed Assistant Surgeon. Directed to investigate relative to small-pox in Mississippi and Crittenden counties in Arkansas, January 14, 1896.

THE MEDICAL NEWS.
A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXVIII. NEW YORK, SATURDAY, MARCH 7, 1896. NO. 10.

ORIGINAL ARTICLES.

THE EARLY DIAGNOSIS OF TUBERCULOSIS OF THE KIDNEY.[1]

BY WILLY MEYER, M.D.,
OF NEW YORK;
PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

IN speaking of primary renal tuberculosis I do not, of course, consider the acute invasion of multiple miliary tubercles as it appears in the course of general miliary tuberculosis. What I intend to discuss is the chronic form of tubercular inflammation which primarily affects one kidney alone.

Let me first emphasize the clinical facts which, although still opposed by a few authors, seem to be well established, viz., that this form of tubercular inflammation is always at first unilateral and descends from the one kidney into the bladder (infecting on its way the ureter), and involves in the beginning one side of that organ only; and that considerable time always elapses before the prostate, with the rest of the genital system and the other kidney, becomes affected. In many instances of commencing renal tuberculosis this one organ alone seems to be attacked by the deleterious inroads of the bacillus Kochii, while the lungs, intestinal tract, bones, and joints are absolutely healthy.

Thus it is evident that if we succeed in recognizing and removing the primary local manifestations of a most deadly general disease, it should be considered a triumph of surgical diagnostics and therapy.

With reference to the etiology, the question naturally first presents itself, How does it occur that a solitary tuberculosis develops in one kidney, or, more strictly speaking, in one of the papillæ of the kidney where the primary focus is always found? The answer is, by embolism. Just as we explain the primary tuberculous inflammation, say, of one of the condyles of the femur or of the tibia by assuming an arrest in a terminal branch of the nutrient artery of the respective bone of one or more tubercle bacilli, so the appearance of a primary renal tuberculosis must also be based on that generally admitted pathological fact, namely, that tubercle bacilli are carried with the blood into the different organs. At one time the bacilli enter the right, at another time the left, kidney.

Many may think that in order to have a kidney infected by the entrance of tubercle bacilli a latent tuberculous deposit must exist somewhere in the patient's body; but this is by no means necessary. We all know that every one of us is exposed to the great danger of inhaling—oftener of swallowing—tubercle bacilli. Unluckily this is still a fact, in spite of continuously improved prophylactic and hygienic measures. If the bacilli be swallowed, infection of the intestinal tract does not follow as a necessary consequence. The infecting micro-organism may be absorbed with the chyle and thus enter the general circulation.

Infection by embolism can take place in any part of the body. No doubt it is a rather rare occurrence to have the bacilli carried into one of the kidneys alone, yet it does occur and certainly oftener than has been heretofore accepted by the profession at large. In the majority of cases Koch's bacillus will settle and find a fertile soil in which to grow and multiply—in the kidneys of those individuals only who inherit the tendency to tuberculosis. A healthy organism—by virtue of the vital energy of each cell-body—will successfully oppose the deleterious inroads of the germ, and it is discharged with the natural excretions.

I wish to mention, in passing, the so-called "ascending" tuberculous inflammation as another etiological explanation of tuberculosis of the genito-urinary system. That the prostate and epididymis in rare instances may be primarily invaded by tubercle bacilli which circulate with the blood also must be admitted; but we have not only the right to suspect, nay, since Schuchardt's[1] most interesting observations, we have in our hands proof of the assumption that tubercle bacilli quite frequently enter the urethra with the gonococci, and may thus primarily infect the prostate or epididymis. By a similar route the female bladder also is subject to the same infection. On the other hand, the prostate or epididy-

[1] Read before the Medical Society of the State of New York at its ninetieth annual meeting, January 29, 1896.

[1] *Archiv f. klin. Chirurgie*, Vol. 44, 2; and *Centralbl. f. Chirurgie*, 1892, No. 47.

mis previously attacked by gonorrhœa in one of tuberculous parentage will often be the so-called "*locus minoris resistentiæ*" to tubercle bacilli carried by the blood. It is a matter of fact that gonorrhœa very frequently precedes primary tuberculosis of the prostate or epididymis.

As soon as the tubercle bacillus has gained a foothold in one of the kidneys destruction begins. A tubercle is formed quietly, without local or general manifestations; slowly it undergoes cheesy degeneration and destroys the renal papilla in which it had developed. Up to this time the individual does not feel or exhibit morbid symptoms. Polyuria may occur, but its true significance is seldom recognized early. Finally the cold abscess with its cheesy masses is evacuated into the pelvis of the kidney, and the urine suddenly becomes turbid and mixed with blood. The cheesy masses, passing down the ureter, will produce symptoms of renal colic. If now the physician makes a careful chemical, microscopical, and bacteriological analysis of the urine, the disease *can* be correctly diagnosed at once, but in the majority of cases one is more likely to think of a renal stone as a causative factor than of primary tuberculosis, and very naturally, too, as the trouble generally occurs in patients between the twentieth and fortieth year. Often the urine is very thoroughly examined, but the staining of portions of the sediment for tubercle bacilli is omitted, or the specimens are stained, but the bacilli are not recognized and the correct diagnosis is not reached. The hematuria, which varies in degree, lasts several days and slowly ceases; the pains also decrease in severity; the urine after a while appears clear and macroscopically normal. The attack is now considered over and the patient discharged.

If, at this stage of the disease, cystoscopy is practiced, a picture is sometimes seen which establishes with absolute certainty the diagnosis of primary descending tuberculosis of the urinary system, even if so far no tubercle bacilli have been detected.

As far as I am able to find in literature, the following observation has not yet been described. On viewing the interior of the bladder the cystoscopist perceives an absolutely healthy surface of the vesical mucous membrane and one perfectly normal ureteral opening. The mouth of the other ureter, however, is injected, and a number of circumscribed, clearly defined, inflamed areas of the mucous membrane can be seen between it and the slightly hyperemic trigonum, leaving the interposed tissue unchanged in appearance, and thus one recognizes with marvelous and astonishing clearness the enemy's steps in a hitherto uninvaded field. I could not compare this picture better than to liken it to footprints in the freshly fallen snow. No other disease of bladder or kidney with which I am acquainted presents a similar cystoscopic appearance.[1] Should the microscope fail after repeated observations to confirm a diagnosis made by the cystoscope, it would be well to inoculate a rabbit by injecting some of the sediment into his pleural or peritoneal cavity, or the diagnostic value of Koch's tuberculin might be tried. In a case at Czerny's Clinic, at Heidelberg, the diagnosis was made by this means, tubercle bacilli appearing in the urine only after repeated injections of tuberculin. On account of the injurious effects of these injections upon the general health of the patient, this method is not to be recommended.

It is scarcely possible that the cystoscopic picture described above could result from any other than a tuberculous irritation. Ordinary pus, not carrying specific micro-organisms, which passes the ureter and bladder after perforation, say, of an abscess containing a small renal calculus, cannot leave similar traces. It is not injurious to the epithelial layers of the vesical mucous membrane; and should slowly growing renal tumor rupture into the pelvis of the kidney, simple hematuria would ensue, but no large amount of pus and cheesy deposits would be found.

In many cases, of course, the picture will not be as clear and pathognomonic as described above. I have seen it so far in two cases only. Especially will it be indistinct where, by previous catheterism, sounding, or irrigation, infection has been carried into the bladder—an occurrence which is very frequently met.

In view of this reasoning, the primary use of the cystoscope cannot be too strongly insisted upon.

Up to a short time ago no means of positive diagnosis in such cases was available, but luckily new, ingenious methods of examination and improved cystoscopic instruments brought forward recently have at last fulfilled a dream that for years has occupied the mind of every medical man interested in this class of diseases. I refer to the catheterization of the ureters, which permits of the bloodless, separate collection and analysis of the secretion of each kidney. In the female sex Kelly's excellent, well-known method should be preferred to others, on account of its absolute

[1] In these examinations I place great reliance in Nitze's instrument, and use no other.

asepsis. Here the bladder is filled with air and the catheter introduced into each ureter with the patient in either the knee-chest or recumbent posture. In the male, Casper's new ureter-cystoscope also enables us to insert the tip of a small catheter into the mouth of each ureter under direct guidance of our eyes, and to push it up toward the pelvis of the kidney as far as desired. I have practiced both methods and cannot praise them too highly. Casper's ureter-cystoscope has been in my possession for the last four months, and in three female and five male patients I succeeded easily in catheterizing both ureters and draining off each kidney separately.[1]

One ought to take great care in these cases—besides proceeding aseptically—not to introduce the catheter too far toward or into the pelvis of the kidney, so as to avoid artificial infection of a healthy organ. If the urine of each kidney has been collected, careful analysis of the same will, in many cases, be an invaluable help in establishing a correct diagnosis.

Thus you have seen that at present we have quite a number of reliable means which, if properly applied, enable us to diagnosticate the primary tuberculosis of one kidney, even in its very beginning, in the majority of cases. The great influence of such scientific progress upon our therapeutic procedures is evident. Only extirpation of the diseased kidney will save the patient's life and save him years of more or less severe illness. In view of the sad prognosis of the trouble in question, this operation seems to me to be clearly indicated. To trust in a spontaneous cure of the disease under a general symptomatic *régime* would be by far too hazardous. The possibility of such a spontaneous cure must, of course, be admitted, but it certainly is a very rare exception and so far not upheld by clinical facts.

On the other hand, by extirpation of the kidney, done as soon as possible, the trouble is not palliated, but actually cured. This point cannot be too strongly emphasized.

If patients, and, as I have frequently experienced, the family physician also, will not consent to such a radical treatment at this early stage of the slow but deadly disease, and prefer to temporize, the removal of the diseased organ, even at a later stage of the trouble, may still effect a cure. The important point is not to wait until a tuberculous inflammation of the genital sphere is added to the descending tuberculosis of the uropoietic system—a course which will happen with almost absolute certainty in the male—not to wait until the other kidney is similarly attacked by an ascending process. The operation *then* will only improve, never cure. It should be remembered that infection of the prostate generally sets in early.

Therefore, in cases of the sudden appearance of the above mentioned symptoms, too much stress cannot be laid upon the necessity of establishing a strictly defined diagnosis as soon as possible, and of carrying out that treatment which alone is the logical sequence of the same, to wit, *early extirpation of the primarily diseased kidney.*

[1] I would refer those who are interested in this subject to an article of mine read before the Section in Surgery of the New York Academy of Medicine, November 11, 1895, which will soon appear in the New York *Medical Journal*, entitled "Catheterization of the Ureters in the Male and Female with the help of Casper's Ureter-cystoscope."

THE RESTRICTION OF TUBERCULOSIS.[1]

BY VICTOR C. VAUGHAN, M.D.,
OF ANN ARBOR, MICH.

OF the 63,000,000 people living to-day in the United States, 9,000,000 or more will, unless something be done to prevent it, die of tuberculosis. In the census year of 1890, 102,199 deaths are reported as due to pulmonary tuberculosis, or consumption. To the reported deaths, not less than 30 per cent. should be added in order to arrive at the actual number. When this computation is made, it will be found that the annual number of deaths in this country from pulmonary tuberculosis amounts to nearly 133,000; I know of no reliable *data* from which we can ascertain the number of deaths from tuberculosis of other organs than the lungs. However, knowing, as we do, that every part of the body—the skin, the muscles, the bones, the nervous system, the abdominal and pelvic viscera—are all occasional, and some of them frequent, sufferers from the invasion of tubercle bacilli, we will hardly be accused of exaggeration when we state that in all probability this micro-organism is directly or indirectly the cause of not less than 150,000 deaths in this country each year.

Leyden gives the ratio between annual deaths and the total number of infected persons as 1 to 7, and Williams states that the average life of the consumptive among the better-to-do classes of England is eight years. Accepting Leyden's estimate, we see that an average of 150,000 deaths annually indicates that the total number of persons in this country to-day infected with tuberculosis amounts to 1,050,000, or one out of every sixty of the population.[2] These

[1] An address delivered (by invitation) before the Colorado State Medical Society, 1895.

[2] The census of 1890 is used as the basis of these statements.

figures are probably too small. Germany has a population equal to about three-fourths that of this country, and Leyden stated before the International Congress of Hygiene and Demography, at Budapest, last September, that the number of consumptives in the German Empire is not less than 1,300,000, and that the annual deaths from this disease in the same country range from 170,000 to 180,000. However, the estimates which I have given are sufficiently large to render the subject of the restriction of tuberculosis worthy of the consideration of every one who is interested in the welfare of the human race. It should, however, be borne in mind that unless some effort is made to prevent it, the mortality from tuberculosis will increase with improved facilities for travel and the greater ease with which the consumptive invalid, even in the advanced stages of the disease, mingles with and infects the healthy.

It should be stated that the figures given above include only those cases in which tuberculosis progresses and causes death. The number of persons actually infected is indeed so large that one hesitates to give it. The records of the autopsies show that not less than one-third of all men have tuberculosis during some period of life. Bollinger found tubercular lesions in 27, and Massini in 39, per cent. of all cases examined. In 200 post-mortems made by Harris, and in which special attention was given to the detection of evidences of infection, the results were positive in 38 per cent. In the examinations made at the Paris morgue, the percentage of cases in which tubercular lesions, active or quiescent, are formed is, according to Bouchard, as high as 75. Biggs, of New York, found tubercular changes in 60 per cent. of the bodies examined by himself. In 125 autopsies made at the Foundling's Home in New York, the bronchial glands were found to be tuberculous in all. Even when there are no indications to the eye of tubercular infection, the presence of the germ may often be shown by the inoculation of guinea-pigs; thus, in eight out of thirty cases, in many of which there were no recognizable tubercular lesions, Loomis demonstrated the existence of the bacillus in the bronchial glands by the inoculation of animals.

Tuberculosis is a disease which is frequently arrested in the first stage, but it is also true that it often progresses through the second stage and terminates in death. At first it is due to an unmixed infection. The tubercle bacillus finds its way into the human body, develops slowly, and in a large per cent. of the cases remains but feebly active or dies out entirely, leaving the lesions so frequently observed in the autopsies referred to above. If the information which we get from these post-mortem examinations of the bodies of persons dead from accidental causes, or from diseases other than tuberculosis, be correct, and I see no reason for doubting the authenticity of statements made by so many men skilled in the recognition of pathological lesions, then it must be true that tuberculosis, so long as it remains an unmixed infection, is not one of the most fatal of the infectious diseases. The history of inoculation tuberculosis, which has been accidentally induced in man, confirms this view. The instances in which surgeons, pathologists, butchers, dealers in hides, children circumcised by tuberculous rabbis, and others have been accidentally inoculated with this disease, are observed with sufficient frequency to enable us to know quite accurately the history of the disease when thus acquired. In these cases the disease remains for many years, often through life, a local affection; its progress is slow, and it seldom produces death.

Although the tubercle bacillus can be induced, under specially favorable conditions, to multiply on artificial media, it is in nature an obligate parasite, and does not reproduce itself outside of the animal body. Obligate parasites do not speedily destroy their hosts. It is not conducive to their best interests to do so, because their continued existence depends upon that of their host, or on their transference to another host. This is true not only of the tubercle germ, but of the bacilli of leprosy and syphilis. Furthermore, man is not so susceptible to the tubercle bacillus as some of the lower animals are. A pure culture of this micro-organism will speedily kill a guinea-pig, while, as we have seen, its growth in man is slow and liable to temporary, and even permanent, arrest.

The tubercle germ, unaided by saprophytic micro-organisms, seldom kills. One-seventh of the human race in civilized countries die of tuberculosis; but one-third more are infected with the germ. Therefore, in the difference between one-third and one-seventh, or in nearly one-fifth of all men, the disease is present at some period of life, but does not cause death. Of the 63,000,000 of people now living in this country, 21,000,000 have been, are, or will be infected at some time, but only 9,000,000 will die, of tuberculosis, leaving 12,000,000 who will be infected, but in whom the infection will not progress to a fatal termination.

In the second stage of tuberculosis the disease

becomes one of mixed infection. Other pathogenic, or even saprophytic, germs are carried into the infected tissues, and, finding there a soil rendered favorable to their growth by the previous specific infection, begin the process of tissue disintegration. It is probable that the many causes of pulmonary consumption which apparently have their origin in attacks of influenza and bad colds are explainable in this way. The individuals are already tuberculous, possibly have been so for many years; the acute inflammation of the respiratory tract brings with it or is due to the secondary infection, and for the first time tuberculosis is recognized. The sudden appearance of miliary tuberculosis after measles and whooping-cough is probably another illustration of the same thing. That this is the case in pneumonic phthisis, there can scarcely be any doubt. Indeed, the post-mortem examination often shows bronchial glands which have evidently been tuberculous for a long time. There has been much said and written about a pretubercular stage; there is no evidence of the existence of any such a condition as a diseased state. On the other hand, the tubercles often exist long before the disease is recognized, and in many in whom no lesion of a tubercular nature is suspected until the autopsy reveals it.

That the bacillus discovered by Koch in 1882 is the primary and essential cause of all forms of tuberculosis, no intelligent and well-read medical man will now deny. Without specific infection the disease does not and can not exist. While this germ does not destroy every body which it invades, and probably does not, unaided, produce death in many, without it no amount of saprophytic infection can cause tuberculosis. Bad colds, influenza, pneumonia, measles, and whooping-cough do not originate consumption.

The exhaustive researches of Cornet, extending through the years of 1887, 1888, and 1889, and since confirmed by others, have revealed the manner in which tuberculosis is disseminated. The air exhaled from the lungs of the consumptive, even in the last stages of the disease, is germ-free. The sputum in cases of pulmonary tuberculosis, the discharges from the bowels when sputum is swallowed, and in intestinal tuberculosis, the urine in case of involvement of this excretory tract, the discharges from tuberculous sores on any part of the body, the milk and flesh of tuberculous animals are the media in which the germs of this disease exist outside of man's body. As has been stated, the tubercle bacillus does not reproduce itself outside the animal body, excepting under certain artificial conditions. The number of tubercle germs in the sputum on the floor or in the cuspidor does not increase ; but in its resting or spore form, it may, under certain conditions which ordinarily exist, retain its vitality indefinitely. The consumptive spits on the floor, and then the sputum dries. The housemaid's broom may scatter the contained germs from time to time ; some will settle on the walls, others on the furniture, and still others on the floor again ; her broom and brush may knock them about from place to place, day by day, and she may consider herself a fortunate maid if, sooner or later, the micro-organism does not find its way into her lungs.

As many of you know, Cornet collected dust from various sources, and tested the same for the bacilli of tuberculosis by the inoculation of guinea-pigs. These studies showed that the dust taken from rooms occupied by consumptives who were in the habit of expectorating on the floor or in their handkerchiefs, frequently contained the bacillus; while the dust from rooms occupied by those consumptives who were careful to use cuspidors, and never spit on the floor or in their handkerchiefs, was free from the germ. The baccilli are transmitted from man to man or from animal to man. The disease never originates in any other way. The transfer is, as a rule, an indirect one, and we are often unable to ascertain the route by which it is made, but we know that every case of consumption comes from a preceding one. Tuberculosis is a disease which is largely due to infected houses. Flick has shown this to be the case in Philadelphia. Cornet found that 62.88 per cent. of all the deaths which had occurred in thirty-eight cloisters during twenty-five years was due to tuberculosis. Baer ascertained that from 40 to 60 per cent. of the total mortality in prisons in Germany may be ascribed to the same cause. These figures show what alarming fatality may follow restriction to infected houses and rooms. Cornet calls attention to the fact that the mortality from tuberculosis is greater in those cities where the largest number of people have no homes of their own, but move about from house to house. In this manner one infected house may shelter and destroy the susceptible members of many families in the course of a few years. According to Cornet, the following figures give the annual mortality per 1000 inhabitants from tuberculosis in the cities mentioned:

London	2.9	Paris	4.1	Wiesbaden	2.9
Glasgow	7.0	Berlin	3.8	Liverpool	6.4

He does not claim that the frequent inter-

change of dwellings in the last-mentioned cities is the only cause of the great mortality, but that it is an important factor.

When the consumptive knows how, and properly attends to the thorough destruction of the germs thrown off from his body, there is no longer any danger of his becoming a centre of infection. Residence in a properly conducted hospital, arranged especially for the care and treatment of tuberculous patients, would be perfectly safe. The danger of infection in such a house would be much less than that to which the traveller subjects himself every time he passes a night in a hotel. In the latter instance one is assigned to a room, the condition of the previous occupants of which is wholly unknown to him. The bed may have been occupied by a careless consumptive who has scattered the seeds of the disease about him. Wherever we go, we are in danger of being infected, but if certain well known rules should be followed in detail, the infected and the uninfected might mingle without danger. The bravest man may hesitate to walk through a jungle which conceals a single savage beast, but the timid one does not hesitate to approach a whole menagerie of caged lions. Cornet has shown by positive demonstration that, of all places examined by him, where people congregate, the one most free from the chance of accidental infection is the properly equipped and kept surgical operating-room. Here one is less liable to infection than he is in the open street or in the best kept hotel or in a private house.

Frequently we hear it stated that only the weak and feeble acquire consumption, and the fittest survive. A more heartless, false, and unscientific statement was never made. If a man with a loaded gun should be placed at every street corner, his eyes covered, and then all the inhabitants of the city marched down the street, and the man with the gun told to fire into the procession as it passes, would any sane man say that only the weak and feeble or morally bad would be injured? Every soldier in battle is not killed or wounded, although all may face the fire of the enemy. Of two men receiving like gunshot wounds, one may survive and the other die, but the chances of life are greatly increased if neither is wounded. The tubercle germ may kill one and not another, but it injures more or less every person who inhales it. It may develop rapidly in one, slowly in another. Its growth may be continuously progressive in one, while in another it may be temporarily, and in a third permanently, arrested. While there are undoubtedly differences in susceptibility with like exposure, with no exposure the most feeble and unfit will not acquire tuberculosis, and with sufficient exposure there is probably none sufficiently robust to remain immune to this disease. To this the people of Colorado should give special thought. Your climate has a well-deserved reputation of prolonging the lives of consumptives, and they come to you from various parts of the world. This would be all right, if these living bacteriological culture-flasks were not permitted to scatter their contents about them. Mentone once had the reputation of being a most excellent place for the climatic treatment of consumption, but the invalid visitors coughed and expectorated on the streets and in the houses, until the disease became fearfully prevalent among the native-born. The following quotation is taken from an article by Bennet, who practiced medicine at Mentone for many years, and who, at the time of writing this article, did not believe tuberculosis to be infectious:

"During the last few years phthisis has become much more common at Mentone, among the girls and young women, than it formerly was, especially among the washerwomen, a numerous class; and contagion from the linen soiled by the sputa of consumptive patients has been suggested as the cause. I am disposed, myself, to attribute the undoubted increase of phthisis in a healthful Southern locality to other causes; to the mere change in habits and occupations. When I first settled in this region, in 1859, nearly the entire population was agriculturally occupied. All the young women of a village lying on a mountain-side a few hundred feet above a property of mine were thus engaged, working at the soil with their father and brother, carrying stones and earth in baskets on their heads. They were fine, healthy, robust girls and women, fed on macaroni, olive oil, and wine, worthy to be *matres hominum* (mothers of men). I often had half a dozen working for me in this way, tripping lightly over the rocks and hillsides, heavily weighted. I employed them at that time with some compunction, which I should not feel now. Times have changed; the Grimaldi girls have all become town workers, washerwomen, seamstresses, servants, and they begin to die of consumption. Is it not because they work in close, badly ventilated, damp rooms, instead of in the open air? Is it not again a question of rebreathed air, not of contagion?"

The authorities of Colorado Springs and other health resorts in this State should profit by the lesson taught at Mentone. I do not propose to discuss the relation of climate to consumption; but if I may be permitted, there are a few facts that have been largely overlooked, and which I believe to be important. A given place may be a good one for an infected person to live, and an equally good one for the uninfected to shun. There is no evidence that climate gives immunity to this disease. Acquiring tuberculosis and arresting its progress when once acquired are different things. The best thing to do is to avoid

the former. The place to avoid infection is not where there are no consumptives, because there is no such spot known in the civilized world, but where the consumptive disinfects the sputum and does not expectorate on the floor or in his handkerchief. It is true that it is not a good thing for the consumptive to inhale new supplies of the tubercle germ from time to time. In this way new areas of lung tissue become involved, and the disease extends ; but, as we have seen, the tuberculous person must especially endeavor to prevent the engrafting of a saprophytic infection upon the specific one already established. Therefore, an aseptic atmosphere is the one in which the consumptive should live; and the more nearly aseptic the atmosphere, the longer, other things being equal, is the infected person likely to live. I will not claim that there is no value in altitude, relative humidity, etc., *per se*, but I do hold that an air free from pyogenic and putrefactive micro-organisms is the one where our patients do best, whether it be on the plains of Egypt or on the mountain-tops of Colorado. Dryness of the air is conducive to the alleviation of consumption, because to the extent to which it is dry the air is aseptic. Sunny climes are beneficial, because bright sunshine is a most potent germ-destroying agent, and its effects extend over large areas. The large proportion of cloudless days which you have here in Colorado constitutes one of the valuable features in your climate. The purifying effects of the sunlight are undoubtedly intensified by the rarity of your atmosphere, due to your altitude. No one can deny the value of climate in the treatment of tuberculosis, and all agree that your climate has proved to be of pre-eminent value in its good effects upon this class of invalids.

However, believing, as I do, that saprophytic infection plays so important a rôle in the progress of tuberculosis, I must emphasize the necessity of attending to local sanitary conditions. There is no part of the earth possessed of a climate so salubrious that man may not vitiate its good effects. After some years of experience in advising tubercular patients in regard to climatic treatment, I have come to the conclusion that I will not send any more of them away from home, unless they will promise to place themselves under the care of some physician whom I know will be willing and capable of advising them in the choice of a residence. I believe that a consumptive who lives in a house well ventilated and well drained in Michigan is more favorably located than he would be living in an unsanitary house in Colorado. Of course, if he can be out of doors most of the time he is better off here; but even then, if he must sleep in a small, unventilated, dirty bedroom, it is questionable whether or not it is wise to advise the change. With organic matter to feed upon, and with heat and moisture, saprophytic germs will thrive and find their way into the lungs of those who inhabit the house which those micro-organisms infest.

All of the preceding is the introduction to what I wish to say as to the restriction of tuberculosis. Fortunately for you, however, the prologue is longer than the body and conclusion of my discourse.

Bearing in mind two points which I have endeavored to enunciate, I will proceed. First, however, let me restate these two facts which I believe to be of fundamental importance. They are as follows: 1. Primarily, tuberculosis is, in many cases at least, an unmixed infection, and in this form it seldom proves fatal. 2. When tuberculosis becomes a mixed infection, its natural course is to terminate in death.

We are to restrict the disease by preventing the primary infection. How can this be done? Only in one way, by the destruction of the infecting agent. The places where the tubercle bacillus is found outside of the human body have already been enumerated. We must stop the sale of milk and meat from tuberculous animals. This can be done by the inspection of animals in the dairy and in the stockyards by competent, skilled veterinarians. The experiments of Ernst and others have shown that milk may, and often does, contain the bacillus, even when no local lesion on the udders exists. No one should be allowed to sell milk without a license, and this should be granted only after the employment of the tuberculin test. Whether any part of the carcass of a tuberculous animal should be eaten or not may be regarded as a question yet unsettled, but none of us would like to eat the flesh of such an animal, and there would be no meat famine should it be wholly excluded from the market. Moreover, if this test were universally applied, the spread of the infection among cattle would be greatly lessened, and from an economic standpoint it would pay. I have great confidence in the tuberculin test as applied to cattle. Only a few days ago I saw it tested on one of the finest herds in Michigan, and every cow which gave a reaction revealed at autopsy a tubercular lesion.

The greatest work must be done in the disinfection of the sputum and other germ-containing excretions from the human body. Much good can be accomplished by the circulars now being quite generally distributed by boards of health,

but this agency is insufficient and incomplete. There are details which even the most conscientious and intelligent are not likely to get from the most explicitly worded printed directions, and these details are all important in the accomplishment of our object. When we recognize the fact that we must teach the unlearned and careless as well as the intelligent and painstaking, the inadequacy of printed directions become all the more evident. To depend wholly upon such information would be like teaching chemistry exclusively from textbooks. The most intelligent student cannot become a skilled bacteriologist with the best library on the subject in the world, unless this be supplemented by practical work in the laboratory. If the trained student need such practical demonstrations, how much more must they be essential to the patient, who generally is wholly without scientific knowledge? The surgeon who has no laboratory instruction in bacteriology continues to lose his patients after operations, by neglect of the details of asepsis. How, then, can we expect the factory girl with tuberculosis to carry out the details of the disinfection of her sputum so thoroughly that she will cease to be a centre of infection? Lectures from the wisest, and books by the most learned cannot, unaided by practical work, make successful farmers or mechanics. The details necessary for the complete destruction of the agents of infection can be taught only by practical illustration. Schools for the instruction of consumptives in the methods of taking care of themselves and preventing the spread of the disease to others should be established. This would result in lengthening their own lives, in rendering them more comfortable while they do live, and would save many others from infection. These schools should consist of model hospitals, where the consumptive would be both patient and pupil.

I believe that every State should establish one or more hospitals for the education and treatment of its consumptives. Possibly it would be better if the general government should undertake this work; and by the proper selection of sites, the advantage of climate would be added to other therapeutical measures employed. These hospitals would have a twofold use. The training of its inmates in methods of restricting the disease would be of untold benefit, and it is now generally conceded that the institutional treatment of the disease is the most successful. Only in such institutions can the dietetic and hygienic treatment be carried out satisfactorily, and all will agree that this is of more importance than the use of medicinal agents. At the Falkenstein Hospital for Consumptives it is stated by Leyden that the cures amount to 24 per cent.; and I am sure that this cannot be equalled in private practice, even when aided by the specially favorable climate of Colorado.

But, says one, the experiment which you propose would be, if carried out, an expensive one. This is true, but is it not also true that we are paying heavy tribute to this plague at present? How much loss in money do the 150,000 annual deaths from this disease entail? How great a financial loss will it be to this country when one-seventh of those now living become its victims, many of them after years of sickness, during a larger part of which time they will be unable to earn their daily bread? I will not attempt to name a money value of these lives. The question is above any financial consideration. It is one of the welfare of the human race.

Has anything of this kind ever been done? Yes, fortunately we have a parallel in the method by which leprosy was eradicated from Europe. Hirsch tells us that after the wars of the Crusaders, leprosy became fearfully prevalent all over Europe. Our ancestors recognized the fact that there was only one way of ridding themselves of this plague. At one time, according to the same authority, there were no less than 1900 leper-hospitals or retreats in Europe. The leper must live in one of them. He could go from one to another; but if he traveled by day he was compelled to wear a distinctive garb by which he could be recognized and shunned; and if by night, he must carry a bell, the constant tinkling of which would warn those whom he should meet. Now, by a much more humane method, we can, and our descendants will, I believe, stamp out tuberculosis. In the plan which I propose it would not be necessary for every consumptive to go to such a hospital, nor would it be necessary for even the incurables to remain in these places indefinitely. The intelligent tubercular patient may live in intimate relation with his family, so soon as he knows and will practice the rules necessary to prevent infecting others. There is nothing cruel in the proposition which I made. On the other hand, it has everything to recommend it from a humane and even a sentimental standpoint. A distinguished German writer on tuberculosis has stated that "the healthy should be considered before the sick." I would say that every comfort should be extended to the invalid, and that there should be no suffering in this world which human skill can relieve.

THE POSITION OR POSTURE OF THE PATIENT OURING PARTURITION, WITH SPECIAL REFERENCE TO THE MERITS OF THE WALCHER POSITION.

By ANDREW F. CURRIER, M.D.,
OF NEW YORK CITY.

In the practice of obstetrics in this country the most of us have become so accustomed to the dorsal position of the patient during the second and third stages of labor that the question is seldom asked, by the average obstetrician at least, whether there is any position which is more advantageous for either parturient or *accoucheur*. Habit enables us all to use with comfort and satisfaction measures and appliances which to others may seem clumsy and ill advised. We are loth to change that which suits us and seems to answer our purpose. Our American women seldom have pelvic deformity to an extent which would prevent delivery by the natural passages, and though it has been asserted by distinguished authority that the average weight of American infants at birth is somewhat greater than that of European infants, even this fact, if it be a fact, does not seem to offer sufficient obstacle to call for radical changes in the present methods of conducting labor. In cases where operative interference becomes necessary, we are accustomed to make use of the lithotomy position, which, while it fixes the pelvis and gives us a basis of support, also diminishes the antero-posterior diameter of the pelvic brim, and hence must theoretically increase the difficulties of delivery. Practically it seldom does; there are few instrumental deliveries attempted, by men of ordinary ability as obstetric surgeons, which are not carried to completion. In view of all these facts, there are many men, of excellent ability in the usual course of obstetric experience, who do not feel the need for the refinements of obstetric knowledge to the same extent as those who practice where pelvic deformities abound. Many physicians, if they acquired these refinements, would forget them in the intervals of their application.

The position with which the dorsal comes most into competition is the left lateral, sometimes called the English, position, which is spoken of with great favor by many of our most experienced obstetricians. It is chiefly applicable for normal, that is, non-instrumental, deliveries, for while instruments of various kinds could be applied in this position they would be used at mechanical disadvantage, and the antero-posterior diameter would be subjected to practically the same conditions of shortening as in the lithotomy position. The only advantages which are claimed for the English position are that the sensibilities of the patient are spared by non-exposure, or supposed non-exposure, of her person during delivery, she is spared the annoyance of being moved about before and after delivery, and it is said the perineum can be better protected against rupture. In regard to the first of these so-called advantages, it is possible to deliver in the dorsal position without exposure; and as to the second, a change to the dorsal position becomes almost imperative if any reparative operations upon the vagina or uterus are indicated after labor is completed, and the annoyance of moving her thus becomes essential. The perineum can be protected in the dorsal as well as in the lateral position.

For myself I prefer to deliver always in the dorsal position unless some objection to that position is offered by the patient.

The proposition has been advanced that if we observe the position of parturients in a social condition which has been uninfluenced by civilization, that is, among savages, or those who were only slightly removed from the animals, we should see the teachings of nature and learn thereby the conditions of position which were most favorable to natural and easy delivery. This presupposes, of course, that nature always impels parturients, in the animal stage of development or the stage which is not remote from it, to assume the position which is most favorable to delivery. As a matter of fact, such a supposition is not correct. Nature does not always direct one to the most favorable position, and even the animals in their experiences in labor would sometimes be benefited if they had the advantage of intelligent advice in regard to the position which they should assume. Among savages we sometimes see the crudest and cruelest attempts to assist nature, which could not fail to produce other than a fatal result to the mother, if not to the child, in any but the most robust physique. In any labor which is at all abnormal, especially if there is disproportion between the fetus and the canal through which it is to pass, the best results must come in those cases in which there is an intelligent understanding on the part of the *accoucheur* of the mechanical principles which are involved in the act of labor and the way in which they are best applied; or in other words, when labor is anything more than a normal physiological act, cultured intelligence is a better midwife than uncultured nature.

Before considering the positions which have

been in vogue in the past, during parturition, it is desirable to recall a few fundamental points, and I refer especially to those cases in which there is no considerable pelvic deformity. The bony pelvis, through which the fetal mass must pass, is not an absolutely unyielding and immovable body—it is provided with a series of joints, with cartilaginous attachments, which, like cartilages everywhere, are capable of more or less distention unless ankylosed by disease. The limit of this distensibility in a given case cannot be specified in advance; it is often greater than is commonly supposed, and this fact is too often ignored in our haste to perform brilliant surgical operations. The following case will illustrate this point:

I was called a few years ago to see a woman in an advanced period of pregnancy, with the view of attending her in her confinement. She was short and deformed, and the antero-posterior diameter of her pelvis so contracted that I could not readily insert two fingers between the symphysis pubis and the promontory of the sacrum. I told her that an operation would be necessary in order to give her a living child, and believed that I had a fine case for cæsarean section. She responded that she had given birth to four living children, all of them being delivered by the breech, and that instruments had never been required. I saw the children, with deformed heads, it is true, but otherwise healthy in appearance. She did not require my services when her labor took place.

Another important point is that the contraction of the uterus, and not that of the abdominal and pelvic muscles, is the essential force in the extension of the fetus; contractions of the latter are often helpful and subsidiary, but they are not the chief factor. A position is seldom essential, however helpful it may be, which brings the abdominal muscles into conditions most favorable to mechanical advantage. On the other hand, it cannot be denied that there often seems to be an advantage in bringing these muscles into play by assuming certain unusual positions. King recently advocated the squatting position as an aid to labor. The analogy from defecation makes it clear that it would sometimes be helpful, especially when the head is near the outlet of the pelvis, and King narrates cases in which by assuming this posture a vicious position of the fetus was converted into a favorable one. It is evident, however, that even this simple expedient would not always be practicable a sensitive woman in the agonies of labor pains would find difficulty in supporting herself and exercising her abdominal muscles, even if she were disposed to make the attempt.

The advantages of position in such an accident as prolapse of the funis must have occurred to all. For this accident the knee-elbow position of the patient and replacement of the cord often serve a most valuable purpose.

Another position for the accomplishment of the same end, which, so far as I know, has not been alluded to by obstetric writers, is the Trendelenburg, and this really anticipates what is to be said in favor of the Walcher position.

In an interesting communication read before the American Gynecological Society in 1880, Dr. George J. Engelmann, then of St. Louis, gave an account, profusely illustrated, of the parturient posture among women of all people, ancient and modern. A careful study of this paper confirms me in the statement already made that it is not safe to conclude that any parturient position is the best and most correct one merely because nature or the custom of unenlightened savages and barbarians has dictated its use. An analysis of this paper reduces the various groups of positions to the standing, the inclined, and the horizontal. In the first, the parturient may be unsupported, supported, or more or less suspended. In the second, she may lie upon a bed or couch of any kind, squat or kneel in varying degrees of inclination. In the third, she may lie upon the back, side, or abdomen.

In all these positions the object which is apparently sought is not merely to facilitate the passage of the fetus through the parturient canal by dilating and straightening it as much as possible, but to mitigate the agony of the process by terminating it as quickly as possible, or by diverting the muscular strain to parts of the body not immediately associated with the parturient act. Those procedures seem best adapted to attain these ends which bring the pelvic joints into the greatest degree of extension—in other words, which lengthen the antero-posterior diameter and render the pelvis as roomy as possible. Of the methods figured by Engelmann, the suspended and the dorsal-recumbent are most effective in this respect. For obvious reasons, the former of these is usually inapplicable. The principle of extension may, however, be borrowed from this crude measure and applied to the recumbent position, and it is the good fortune of Walcher to have recently called the attention of the profession to its importance, more especially as an expedient which would obviate the necessity of symphy-

siotomy in cases in which that operation would otherwise be required.

Let us now turn to the evidence concerning the mobility of the pelvic joints, which will also be found to have a direct bearing upon the assertions of Walcher. In a paper by Matthew Duncan published in 1854 (*Dublin Quart. Jour. Med. Sci.*, 1854, XVIII, p. 60), it was stated that in the guinea-pig there was a separation of the ligamentous tissue at the pelvic symphysis during parturition of an inch or more, which was also accompainied with a relaxation of the tissues of the anterior or inferior portion of the sacro-iliac joint, and more or less freedom of motion. In the cow also, as shown by Barlow (*Edinburgh Monthly Jour. Med. Sci.*, 1854, p. 83), there were enlargement and thickening of the great sacro-sciatic ligaments in the latter part of pregnancy, with lengthening and slackening of the same. This enables the sacral joints to move more freely, the ilia moving freely on the sacrum in an antero-posterior direction analogous to the flexion and extension of the limbs, hence producing enlargement of the genital passage.

These investigations upon animals are of great importance in suggesting analogous changes which must more or less frequently take place in the pelvis of the human female during parturition. But Zaglas had already, in 1851, showed (*Edinburgh Monthly Jour. Med. Sci.*, 1851, Sept., p. 289) that in the human pelvis there is motion of the ossa innominata in an antero-posterior direction; that when the body is erect the promontory of the sacrum is least projected into the brim of the pelvis; that its apex is therefore thrown forward, diminishing the outlet and relaxing the sacro-sciatic ligaments.

Duncan, therefore, feels warranted in saying that in the latter half of pregnancy there is relaxation of the pelvic joints. This statement is confirmed by observations of Mme. Boivin and Chaussier, the former noticing a separation of the pubic bones during parturition to the extent of one inch. Boyer also noticed a separation of the sacro-iliac joint, to the extent of half an inch.

Similar observations were made by Smellie, Diemerbroek, and Denman. Mme. La Chapelle even mentions dislocation of the ilium upon the sacrum during labor; and others have observed simultaneous dislocation of both ilia.

"These alterations in the dimension of the brim and outlet," says Duncan, "by movements of the pelvic joints, are not insignificant, but the reverse, and can be confirmed by every obstetrician of experience." When the limbs are flexed upon the pelvis the outlet of the latter is increased, but the inlet is diminished.

The sacrum may therefore be supposed (Duncan) to have a motion around an imaginary transverse axis, the promontory advancing downward and forward, while the axis moves in the opposite direction, and *vice versa*. In the non-pregnant woman a movement downward of the promontory of two millimetres diminishes to that extent the conjugate diameter of the superior strait, while the apex of the sacrum by a corresponding movement is displaced upward by four millimetres, increasing the tension of the sacro-sciatic ligaments and the dimensions of the inferior strait.

These movements are habitually seen in defecation, but offer the greatest interest in women during parturition. There are raising and lowering of the pubic symphysis, the ossa innominata being mobile upon the sacrum, or, if the latter is considered as mobile, it may be regarded as rotating around an imaginary transverse line passing through its second vertebra. By elevation of the pubic symphysis, or inclination forward of the promontory, the angle of inclination of the pelvis is lessened and the conjugate diameter of the superior strait is diminished by four to six millimetres.

These anatomical investigations and conclusions concerning the variations in the conjugate diameter of the pelvis, according as flexion or extension is practiced, have been confirmed by various observers. Ahlfeld investigated the subject in 1876, and showed that the position of extension (practically the Walcher position) was used in Italy as early as the last century (*Schmidt's Jahrbücher*, 1876, B. 179, S. 185).

Hermann Meyer reached the same conclusion in 1878 (*Arch. f. Anatomie und Entwickelungsgeschichte*, 1878, p. 8). Crouzat, in 1881, found by extension and flexion of the pelvis in cadavers that a variation of eight millimetres in the antero-posterior diameter could be obtained.

Farabœuf, Klein, Walcher, and Jewett have made similar investigations, with practically the same results. I have carefully examined the papers of all these writers, and find their statements harmonious, as above stated. If, therefore, limited mobility is found in the pelvic joints of the cadaver and the non-impregnated woman, much more should we expect to find mobility in the joints of the parturient woman. The statements of Walcher are therefore based upon substantial anatomical facts. Walcher has been considered

an enemy by the advocates of symphysiotomy, especially by Varnier, who wrote a long paper in its defense as compared with the Walcher position ("*Les bassins rétrécis sont ils dilatables sans symphyséotomie*," *Ann. de Gyn. et d'Obst.*, 1894, XIII, 428). That he is the enemy of symphysiotomy is denied by Walcher; but inasmuch as in the five hundred and fifty labors which he annually saw at the maternity at Stuttgart there had been no cases requiring symphysiotomy (one case in 1894 requiring cæsarian section), all parturients with narrow pelvis being satisfactorily treated by means of the position of extension, with possibly the addition of some operative measure less severe than symphysiotomy, he could not be expected to favor the latter, as there is at least the possibility of ankylosis or a movable joint as a consequence, in addition to the danger to life (Morisani, the most brilliant and experienced of all who have practiced it, giving at the Rome congress, in 1894, a mortality of nearly 12 per cent. for both mothers and children).

There is also to be considered the danger to the urethra, bladder, and vagina (*Cent. f. Gyn.*, 1894, p. 584). Walcher's thesis in regard to the position of extension, the so-called *Hangelage*, was made in 1889 (*Cent. f. Gyn.*, 1889, LI, p. 892), and was that the conjugate of a narrow pelvis was not a constant quantity, but might vary according to the position of the woman. If a woman were placed in the dorsal position, the legs flexed on the thighs, and the latter on the body, the body being somewhat elevated, the promontory of the sacrum may be readily reached by the finger in the vagina. In that position the conjugata diagonalis, according to different observers, measures from 9.7 to 10.4 centimetres. If now a pillow be laid under the sacrum and the legs allowed to hang downward, over the edge of the bed or table, as far as possible, the promontory may be felt receding as the knees drop, and the conjugate will then measure 10.5 to 11.6 centimetres. Six observers are mentioned who made a series of measurements under these conditions, and they observed a gain of 8 to 13 millimetres. The knees being again raised and the pillow removed, the original measures were obtained. A gain of 1 centimetre may therefore be obtained in the antero-posterior diameter between extreme flexion and extreme extension; it is sometimes less and it is sometimes much more.

What is the practical application of this fact? This question is best answered by reference to the reports of those who have made use of Walcher's suggestions. Aside from Walcher himself may be mentioned Kalt, Wehle, Fehling, and Dührssen.

Kalt (*Cor.-blatt f. schweiz. Aerzte*, Basel, 1894, XXIV, 652) described in detail three cases:

1. Vpara, 31 years of age; requiring assistance in her first, third, and fourth labors. After a very slow first stage the Walcher position was used for three-quarters of an hour. The head then entered the pelvis, passed the promontory, and 15 mintues later the child was born without further assistance.

2. IIpara, 33 years of age; first labor instrumental. In the second, after the head had engaged, the Walcher position was used, and in one and a half hours a large child was born without further assistance.

3. IIpara, 34 years of age; first labor normal. Labor progressed slowly, a foot presenting. Walcher position, living child born without further assistance.

Kalt concludes, therefore, that the position is useful in generally contracted pelvis, or with a short conjugate diameter, to avoid the high forceps operation or symphysiotomy.

Wehle (*Arch. f. Gyn.*, XLV, 322) reports eight cases, seven of them having a narrow or a flat pelvis. The eighth case was an VIIIpara, in which the Walcher position was used after the head had been delivered, the shoulders being detained; delivery quickly resulted. The position was also used with operations for version, for extraction, for extraction after craniotomy, and for the high-forceps operation after symphysiotomy. It enabled Wehle to deliver with forceps after attempts at delivery in the dorsal position had proved futile. Wehle concluded that the best results from this position were to be obtained with a dilated os and intact membranes.

Dührssen advocates this procedure as an adjunct in operative measures which are necessitated by a short conjugate.

Fehling (*Münch. med. Wochen.*, XLV, 1894, 861) advocates the Walcher position as an adjunct to the expression procedure of Hofmeier, for the delivery of the after-coming head, for high-forceps operations, and in cases in which there is a short conjugate. He so elevates the mattresses that the requisite extension will be obtained with the legs covered in the bed, a modified Trendelenburg posture. He narrates the following three cases:

1st. IIIpara, 28 years of age, with a generally contracted, flat pelvis. Her first labor was a severe instrumental one, the child being born dead. In her second, the position was transverse, version was performed, and a dead child was the result. In her third, a bougie was intro-

duced to bring on labor, this being followed by rupture of the membranes. On the second day there were weak pains, on the third and fourth none, on the fifth they were occasional, and on the sixth they came every ten minutes. From 8 to 12 P.M. the Walcher position was used, at 12.10 the head engaged, the membranes again ruptured, and at 12.40 a living child was born in the first vertical position. The conjugate diameter measured 9.8 centimetres.

2d. IIIpara, 25 years of age, with simple flat pelvis. Pains were intermittent in character for six days, and on the seventh, the os being moderately dilated, the Walcher position was assumed, delivery then resulting after three hours.

3d. Ipara, 25 years of age, generally contracted pelvis. After labor had continued several hours and moderate dilatation had resulted, the Walcher position was resorted to. At the end of five hours there was a decidedly febrile condition of the patient, and delivery was concluded with the forceps.

The authors who have been quoted include all the literature upon this subject, so far as I have been able to find it; and as several of them are men of vast obstetric experience and honorable reputation their indorsement of this contribution to the mechanics of labor may be considered important.

The only discordant voices come from those who seem to fear that in some way or other symphysiotomy will suffer by comparison with this simple and usually harmless procedure.

What, then, are the indications for the use of the Walcher position, and what its objections?

1. Cases of protracted labor in which the dimensions of the pelvis are normal or the antero-posterior diameter is somewhat shortened, the head being above the brim. The patient being placed in the position of extreme extension for an hour or more the pelvic joints may become so relaxed, or the antero-posterior diameter lengthened by the necessary half-inch, that the head will engage and labor be terminated normally or with forceps; the high forceps, version, or symphisiotomy being avoided.

2. Cases in which version, either cephalic or podalic, has been performed, or footling or breech cases. The flat pelvis, the generally contracted pelvis, transverse positions, occipito-posterior positions, are in this category. The cases which were quoted show that in some instances labor will be terminated naturally, and that in others the forceps must be used as an adjuvant.

3. Cases in which some form of operative procedure has already been adopted without success. It has thus far been used after high-forceps operations, version, symphysiotomy, craniotomy, and low forceps, and it will probably be shown to have a yet more extensive field.

The length of time during which this position may be used to advantage depends upon the effect which it produces upon the patient. It has been shown by those who have used it that it may be discontinued and re-employed without disadvantage, and sometimes with positive advantage.

After the legs have been suspended half an hour or an hour, it would usually be desirable to discontinue the position for a time, since it is tedious and may cause interference in the venous circulation of the legs and thighs. After a rest of an hour, the position can be resumed if necessary.

The application of the forceps in this position will probably be found less easy than in the classical lithotomy position. It may be that this difficulty can be remedied by placing the patient in the Trendelenburg position, in which the condition of extension would still be preserved.

The contribution of Walcher to practical obstetrics is certainly a valuable one, and will often prove as useful as it is simple and harmless.

ENURESIS.[1]

By W. F. MARTIN, M.D.,
of Colorado Springs, Col.

Perhaps no minor ailment of childhood is more annoying to parents, and particularly to mothers, than is a persistent incontinence of urine in a child. The degree of severity may vary from an occasional wetting of the bed to a constant dribbling of urine day and night, making of the unfortunate victim an object both foul-smelling and repulsive.

It is not the object of this paper to describe those cases in which some anatomical defect, either congenital or acquired, exists, but rather to briefly speak of the more common causes, and what have seemed to me to be the best methods of treatment.

That heredity has a bearing on this subject is made manifest, not only because occasionally one secures a definite history of similar antecedent trouble in the parents, but especially from the fact of its frequent occurrence in several children of the same parents. Of the constitutional, predisposing factors may be mentioned anemia, tuberculosis, chorea, rachitis, and indeed any disorder which chronically tends to

[1] Read before the El Paso County Medical Society, Colorado, November 13, 1895.

keep the system in a lowered or depraved condition. The importance of securing and maintaining a thoroughly healthy gastro-intestinal tract in this as in so many of the diseases of children should always be borne in mind; for certainly, when by improper or irregular feeding the digestive organs become disordered, an aggravation of any tendency to enuresis is assured.

The local condition should not be overlooked: phimosis, adhesions between the foreskin and the glans penis in the male, and possibly adhesions about the glans clitoridis in the female; also the presence of a vulvo-vaginal catarrh, an anal fissure, or irritation from pinworms, should all be remembered as possible aggravating, if not determining, causes of this malady.

An examination of the urine ought never to be neglected. An over-acid or excessively alkaline state of the urine may alone cause the incontinence; and the possibility of diabetes or Bright's disease, stone in the bladder, or cystitis being present will be remembered, if by a systematic examination of the urine evidence toward any of these diseases is found.

Remote reflex causes have of late years been brought more prominently to notice. The relation between adenoid growths of the naso-pharynx and enuresis has been sufficiently often observed to make it seem probable that in some instances the one somewhat influences the other, or both have some underlying common cause. Epilepsy, of traumatic origin, seemed related to enuresis in one case that came under my notice. Dr. Gould has given us unmistakable evidence of the possibility of eye-strain causing this condition. He cites a number of such cases in the Medical News of December 15, 1894. Perhaps when all such possible causes have been eliminated, we shall have to fall back to that most common of all causes, which for lack of a better name we term the "neurotic diathesis," or an unstable or perhaps an unevenly balanced nervous system.

We must remember, as Money puts it in his work on Disease in Children (p. 380), "the great frequency of incontinence is an excellent illustration of the causes of infantile nervous pathology, that the cord is dominant and cerebral inhibition subsidiary. . . . The child is much more a machine of reflex activities than the adult." We can then see how with a naturally heightened spinal action a slight increase in the usual stimulation given by the urine to the afferent nerve endings at the neck of the bladder, and this continued for a little while, will engender a *habit* of incontinence, especially when, during sound sleep, the normally slight controlling inhibition of the brain is still further lessened.

Prognosis.—The prognosis of these cases as to ultimate cure is fairly good. Most of them will regain control of the bladder at or before the time of puberty, as the domination of the brain, and with it the volition, over the cord and the purely reflex actions, develops.

Some cases, however, do not get well without treatment. To utterly neglect such cases, hoping that, when 13 or 14 years of age shall have been attained, the affliction will be cured by nature, is only in that degree to strengthen a habit which, if the enuresis should not be cured then, will be yet more difficult to overcome. Besides this, many years of most annoying discomfort may be spared, even these self-curative cases by judicious treatment.

Treatment.—The remedy for any one of the local causes which have been mentioned will suggest itself. Phimosis should always be relieved, but I believe that circumcision is not always necessary. Many foreskins that seem irreducible can by steady backward pressure be made to uncover the glans penis and permit the accummulated smegma to be removed, adhesions to be broken, and the parts thus uncovered to be cleaned and oiled. If such a procedure be done once a week for a few times, the necessity for circumcision will be obviated.

I have seen large numbers of children, and many with apparently tight foreskins, but I have never failed to retract the prepuce in any such case when attempted in a child under five years of age. There are many surgeons who hold that circumcision is desirable in children in any case; with such I have no quarrel; but that it must be done necessarily for purposes of cleanliness, I cannot maintain.

A means of relieving these cases which is very commonly neglected is the regulation of the diet. *Tea* and *coffee* are often given to children; and in the larger cities, where beer is so commonly used at the table, not infrequently do we find it given to them also. I have known of one instance where beer was given to a child seven months old. These beverages should be absolutely interdicted. No child under puberty should be permitted to indulge in tea, coffee, cocoa, or any alcoholics. When we consider the pronounced effect that such beverages have on the nervous and genito-urinary systems, we can see how baneful the results of indulgence in them may be. In addition to this restriction of the beverages used,

it is wise, it seems to me, to limit as much as possible the use, by these children (and it were better for all children), of sweets and pastry, such as candies, cakes, pies, jams, jellies, and sugared preserves.

By doing this the stomach and intestines are kept in a better condition, and that important factor which we call the general health of the child is maintained. Of the medicinal agents advanced, nux vomica has not been of advantage in my hands, though advocated by some. In the few cases in which I have tried it, it has seemed rather to aggravate the condition by its stimulation of the reflexes. The bromides, which theoretically ought to be indicated, seem not of themselves to be of much benefit, for while they deaden the activities of the spinal reflex centres, they also deepen the sleep and so lessen the cerebral inhibition. Ergot, when the sphincter vesicæ is the chief delinquent, is certainly of benefit; but as this alone is not commonly the cause, we find more benefit from it as an adjuvant to other means. Phosphorus, while in a sense a nerve food, is rarely indicated for the condition of enuresis alone; but when this state is associated with the general condition of malnutrition which we call rachitis, it is clearly indicated. I have seen one case where this remedy given for the rachitis present was evidently of decided value in relieving the incontinence; for when the phosphorus was temporarily stopped, the incontinence, which had been controlled by it, recurred, to be again controlled by its renewal. Iron and cod-liver oil will be called for only as the system at large demands them. Belladonna or its alkaloid atropine will control most of these cases, if pushed to its full physiologic effect, *i.e.*, to a beginning scarlatiniform rash. This will often require very large doses. To a child 4 or 5 years old $\frac{1}{50}$ of a grain of atropine in divided doses may be given; generally not more than $\frac{1}{400}$ should be the commencing dose. If only nocturnal enuresis exists, the alkaloid is given at bedtime, and increased by giving it oftener, say four and two hours before, as well as at bedtime, until either the urine is controlled or the belladonna rash appears. Bladder control having once been secured, the dose necessary is maintained for some fair period of time (several weeks), and then gradually reduced.

In a few cases, where used by me, beneficial effects seemed to be secured by the use of the fluid extract of sweet sumach (*Rhus aromatica*), given with equal parts of glycerine and water (℥ i of the mixture), three or more times daily, the last dose at bedtime. In those cases that do not tolerate the belladonna well, this should be given a trial.

When the trouble is nocturnal only, the fluids ingested toward night should be strictly limited. The evening meal should be as dry as possible, and no fluids given thereafter. As a consequence the urine will be more concentrated, and probably more acid, yet the gain in the lessened volume and lessened pressure will more than compensate for the increased acidity. It seems to me helpful also in these cases to have the foot of the bed, in which the child sleeps, elevated so that its shoulders shall be lower than its hips, and consequently the urine will collect at the fundus rather than at the more reflexly sensitive neck of the bladder. A small pillow for the child's head is perfectly allowable. As these children generally sleep very soundly the inconvenience occasioned by the position of the bed will scarcely be noticed.

At the time the parents retire, the child (who will have been asleep several hours) should be awakened and urged to empty its bladder. The parents can also learn whether, during these earlier hours of sleep, the child has already wet the bed or not. Generally, it will be found that the incontinence occurs later in the night. The bedclothing should be sufficiently warm, and if the child be prone to kick and toss about at night the bedclothing should be more carefully secured by pinning with large safety-pins to the mattress or otherwise, and the child should be clothed with a single-garment night-dress which encases the feet as well as the body. In this way a chilling of the surface of the body, with consequent proneness to reflex contraction of the bladder, will be avoided.

It is decidedly helpful for these children if once a day they receive a tepid or warm bath, followed by cool or, better, moderately cold sponging quickly applied over the body generally, and especially cold sponging down the spine, followed by brisk rubbing and drying of the body. The atmosphere of the room in which the bath is given, however, should always be warm, else the bath may do more harm than good. In the summer-time, sea-bathing may advantageously take the place of the home bath for older children.

Should the age of puberty be passed without control of the bladder having been secured, a much more serious problem will present itself. Diet, hygiene, and medicine may all fail us then, and why? Because by frequent reflex habit the

bladder has become intolerant of more than a few ounces of urine, and when these have collected the bladder becomes fully distended and empties itself during the night and demands frequent attention during the day. In such cases the bladder must be forcibly but gradually distended until capable of holding an amount commensurate with the age of the patient.

APPLICATION OF X RAYS FOR EXHIBITING INVISIBLE OBJECTS IN MOTION.

BY EDWARD P. THOMPSON, M.E.,
OF NEW YORK.

DR. MCKAY, of the Packer Institute, Brooklyn, N. Y., tested my idea termed a scheme in the *Electrical Engineer*, New York, as to the possibility of exposing upon a fluorescent screen the shadows of invisible objects in motion. We saw in what is conveniently termed a kinetoskotoscope the motion of the bones of the fingers when bent backward and forward, the shadow of the rest of the finger being faint. The result was so successful that I noticed a curious feature which was not known to me before, and that is that the bones appear in an end view to be at the back of the finger, and very thin measured from the back to the front. There is a reason for this, I suppose, in that the inner side of the finger should be more like a cushion, so as to be better able to handle objects. An experiment was also performed consisting in opening and closing a pair of pincers which were absolutely invisible to the eye, but the shadow of the moving parts was clearly visible upon the screen. A chain was shaken back and forth; and the separate links moving relatively to each other were clearly visible. These experiments would prove that with the present condition of the X rays the skeleton of a fish could be seen to move backward and forward in the act of swimming, as well as the skeleton of all small objects while in motion, and performing the functions of life. I think that some of the best objects to be looked at while in motion would be, for instance, a bird, through which the rays so easily pass except as to the skeleton. All youthful forms of life could be examined, very probably, by this means, and the motions exhibited. I have for two or three weeks been trying different kinds of experiments, and I find that certain precautions are necessary in order to obtain the best results. In the first place, it is perhaps necessary to show just how I made my fluorescent screen, because I find that others have tried to make it by crystallizing the chemical barium platino-cyanide from a solution upon a sheet of paper. Others merely pressed the crystals upon a surface like filter-paper. Such screens are of little value, especially as the substance then fluoresces blue, which is nearly invisible, and only shows in spots.

By the following means the results are so excellent and the screen is so luminous that the shadows are clearer than in the X-ray photographs: The cyanide should be powdered to the finest dust possible. Then some of the clearest colorless varnish should be put upon a piece of tracing-cloth, because the same is so strong, and so transparent to the fluorescent light which is produced. The powder may now be mixed very thoroughly and intimately with the varnish, so as to make a homogeneous mass, in quantity sufficient to spread over the cloth to a thickness of about $\frac{1}{8}$ of an inch. This is mentioned because experimenters are likely to make the layer too thin. The reason for powdering the material is to produce a maximum amount of reflecting surface. The object of the varnish is to hold it together, and yet permit the reflected rays of flourescent light to become visible. The varnish should then be dried, but not necessarily perfectly dried. These directions should be followed very closely for good results. The end of the tube which is directed toward the Crookes tube, and which contains the screen, should be covered with photographer's black paper used for wrapping up sensitive plates. Either side of the screen may be directed toward the Crookes tube. A very important precaution is to perform the experiments in a rather dark room. It may be light enough to be able to see objects, but if the room is very light, the eyes are not used to darkness, and therefore the experiments are not satisfactory; but if the room is quite dark, the screen in the closed tube appears immediately, upon putting the eye to the hole in the tube, to be perfectly luminous. It will be more luminous under these precautions than luminous paint which has been held in the sunlight and brought into a dark room; and yet if performed where the eyes are exposed to the daylight the experiments are not so satisfactory. Another precaution is to have the electrical apparatus so arranged that the phosphorescent light from the Crookes tube is steady, which may be done, of course, by means of Leyden jars or other condensers.

My idea of this new use for X rays was conceived and attested on Feb. 1, 1896.

CLINICAL LECTURE.

CARCINOMA OF BREAST.—ACUTE APPENDICITIS.[1]

By CHARLES McBURNEY, M.D.,
OF NEW YORK;
PROFESSOR OF CLINICAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

CASE I.

GENTLEMEN: The patient upon whom I propose to operate to-day has a carcinoma of the breast. The operation which I shall perform is one, a description of which was almost simultaneously published by Halsted, of Baltimore, and Willy Meyer, of this city. In this operation, not only the diseased, but also the surrounding tissue which is most likely to contain diseased elements, is removed. The operation provides against the thing which is the most discouraging in surgery—*i.e.*, the recurrence of malignant disease after operation. I say it provides against it, and by that I mean that it provides against it as well as this can be done by any known means. I have done about twenty operations of this kind. All of these patients made a good recovery from the operation. One of them has since died from extensive intrathoracic carcinoma. I shall explain the method of operation as I proceed with it. This redness of the skin is not due to the disease, but is the result of the preparatory soap application, the skin of some individuals being particularly susceptible to such irritants. You see that the whole left breast is involved in the malignant disease, but some of the skin appears to be entirely healthy. There appears to be no skin indurations. The axilla contains well-developed, enlarged glands, but these are quite loose. Careful examination above and immediately below the clavicle fails to show any enlarged glands there. The operation, that has been universally done for many years now, has been the free incision including the nipple, the dissecting back of the flaps widely, removal of the entire breast, and the extension of the incision into the axilla and the removal of its contents. This operation was a very great improvement upon those which had been previously done; nevertheless, when the disease has extended into the fascia or muscle, even such an operation must necessarily be very incomplete. In all cases there is a very strong tendency for carcinomatous disease of the breast to follow the lymphatics in certain definite directions. One of these is into the lymphatics of the axilla, and another, and perhaps still more important one, is through the lymphatics of the pectoral fascia. Hence the operation which I propose to do is founded on a most rational basis—the removal of those parts liable to have become infected in the way just described. So far the results of this operation have justified it. The operation is somewhat difficult, and occupies considerable time, but the patients bear it very well. In fat subjects it is somewhat more difficult of performance. In this case the skin around the nipple, while not exactly indurated, has a peculiar "pig-skin feel," and hence we shall be careful to remove it. In making the incisions in such cases we must not be hampered by considering how the wound is to be closed by skin-flaps. If after the thorough removal of all diseased tissue, the skin-flaps can be brought together, well and good; if not, then it cannot be helped; all of the disease must be removed regardless of the mode of closing the wound after the operation. Secondary skin-grafting is most satisfactorily resorted to, to cover any deficiency left at the time of operation.

I begin by including the breast and a considerable portion of the surrounding skin in a large elliptical incision; the two sides of the ellipse unite and extend up into the axilla, and then another incision is made from the clavicle until it meets the first wound. The flaps of skin are to be made as thin as, in the judgment of the surgeon, they may be and still survive. Of course, if they are made too thin, the vitality of the flaps will be destroyed, and they may necrose. The small flap made by the axillary and clavicular incisions is dissected back so as to expose the pectoralis-major muscle. Having now uncovered the entire field of operation superficially, we shall proceed to remove the breast and muscle *en masse*. I prefer to begin from the outside and dissect inward, including the axilla in the dissection. I am now dissecting down to the edge of the serratus-magnus muscle, after which I shall follow the edge of the latissimus-dorsi muscle. On reaching the axilla we must be very careful in our dissection. The best way, I think, is to find the vein first, and then dissect from this point as a landmark. Where it is possible to leave important nerves, such as the one going to the latissimus dorsi and the long thoracic, it is well to do so. I find that it can be done in the present instance, and, as you see, the amount of connective tissue remaining upon them is very minute. There are many venous branches from the axillary vein; we should carefully ligate these with a double ligature, and then divide them between the ligatures so as to save as much blood as possible. I think you can now appreciate the value of this new method of operating, for you can see several large glandular masses infiltrated with carcinoma which, according to the older method of operating, would have been partially concealed by the pectoralis-major muscle. Moreover, if this muscle were intact, the operator would be working in a small and steadily contracting space, so that it is easy to understand that the removal of all diseased tissue under such circumstances is well-nigh impossible. Now, I pass my finger under the pectoralis muscle, and divide it near to its point of insertion without any danger of wounding important vessels. This exposes the pectoralis-minor muscle, which is likewise divided with the finger underneath, protecting the subjacent parts. Having dissected away all diseased tissue from the vessels, and divided the last muscular attachments, we have only to sever the remaining connective tissue, and we can remove all in one piece. Not only have I removed the muscular tissue, but the fascia which lies over the muscles, for this fascia is extremely liable to be the seat of a recurrence of the disease. Those of you who have seen some of these patients will

[1] Delivered at the Roosevelt Hospital, New York, Feb. 15, 1896.

remember that there is no stiffness after the operation, although there is a slight diminution in muscular power—in other words, the anterior fibres of the deltoid enable the patient to carry on all the forward movements of the arm. The wound has been irrigated with normal salt-solution, and has now been rendered dry and clean. Some of these cases can be safely closed without drainage, but as it is impossible to say just when this can be done, I prefer to provide drainage in all cases. It serves to remove what serum and blood may accumulate, and if the tube be removed on the second day the healing process will not have been at all retarded by the use of drainage, while it has furnished an additional safeguard. I find that the flaps will come together, and close the whole wound without difficulty. Having adjusted the sutures and repeated the irrigation through the drainage tubes with the salt-solution, the final step is the application of the dressing. This should consist of a large number of "handkerchiefs" of gauze so applied as to make uniform pressure over the wound. Over this is placed a liberal supply of absorbent cotton, and the whole is firmly held in place by a binder and a number of broad roller bandages.

Let us now make a section of the breast that has been removed. You see here a characteristic carcinoma. It is not very hard, but it represents a rather rapidly growing type of tumor. Section of the axillary glands shows them to be very thoroughly infiltrated with carcinoma. Although, therefore, this operation is long and difficult, and trying to the patient, these objections must have but little weight when compared with the liability of the disease to recur when imperfect operations are done. Dr. W. S. Halsted has had fifty cases, operated upon in this manner, with no death.

CASE II.

This man presents an interesting history. He is 28 years of age, and has never had any abdominal disease before. Last Monday he was seized with some abdominal pain, but he did not go to bed, and there was no fever and no vomiting. He has been going about, though not at work, every day since then (now five days), and he walked into the hospital last evening. At that time he was leaning over to the right side, but he did not make much complaint. His pulse was only 80, and his temperature 98° F., and there was only slight tenderness in the ileo-cecal region. He certainly then did not have urgent constitutional symptoms. At 10 P.M. he vomited, and at midnight he had a chill, followed by a temperature of 101.4°. The pain increased in the iliac fossa. His temperature this morning was 101.4°, and a short time ago 101.6°. You see that the abdomen is not distended, although it is a little more rounded than normal. I find on examination excessive tenderness over the ileo-cecal region, and also a tumor, measuring about 3¼ inches in length. It is close to the outer part of Poupart's ligament, and extends a considerable distance in the direction of the umbilicus. This tumor was not present last evening. One may quite accurately estimate the pathological process that has been going on here. The patient must have had one of two conditions—he either had at the beginning a perforation of the appendix, with a small amount of suppuration, closely hemmed in by adhesions, thus accounting for the slight constitutional disturbance, or else there was originally a suppurating condition inside of the appendix without perforation. One of these conditions must have existed last night at the time of his admission. At the time he vomited last evening, either the pus already there burst through the adhesions, and invaded a fresh portion of the peritoneum, or else the appendix ruptured. Undoubtedly, we have here suppuration, indicated by the presence of this tumor, which has so rapidly formed, and by the signs which have preceded it. The tumor is often formed merely by excessive inflammatory œdema in cases of slowly developing tumor; but where it has formed as rapidly as in this case, you may be very certain that suppuration is present.

In such cases as this, it is well to make the incision pretty well to the outer part of the abdominal cavity. We can then irrigate and dress the part with the greatest ease. If we should approach it close by the side of the rectus muscle it would be much more difficult to treat. I have now divided the external oblique aponeurosis and muscle and the internal oblique and transversalis. I observe that the fascia transversalis is a little thickened by the adjacent inflammation. I cannot be positive, of course, whether suppuration has reached the abdominal wall at this point or not; one can rarely be positive on this point in any case. We shall therefore enter very carefully, for fear of injuring the intestine. I have opened into an abscess cavity, and now feel with my finger a concretion in it. This breaks down very readily, and we find that the nucleus is a pin. The abscess is very thoroughly shut off from the general peritoneal cavity.

I once saw a case of appendicitis occurring in a child of eight years. He was brought to me with a history of inguinal hernia, and he certainly had the signs of it. I operated upon him for inflamed hernia, supposing there was a mass of omentum in the sac which could be tied off. On reaching the sac a tumor about one inch long and three-quarters of an inch in diameter, containing two pins, was found. On dissecting further I found that the tumor was the appendix, which had come down into the inguinal canal. In another case I removed an appendix containing a concretion. When it was placed in water it dissolved, and I found in it four shot.

I have found enough in this case to account for all his symptoms. Shall I now extensively separate adhesions to see if there is anything more, or shall I simply leave this free opening with the confidence that if there is any more pus it will find its way into this opening? There are no indications that pus exists in any other part of the abdomen, and to break down the abscess wall would expose the patient to unnecessary risk, such as the opening up of a considerable extent of non-infected peritoneum and handling it. Without care, the operator may readily make a small break through the abscess wall in a case like the one before us, permitting a loop of fresh intestine to enter the abscess cavity, and this accident might give rise to a fatal peritonitis. The wound we have made here will be kept irrigated and lightly packed with gauze, and will fill up in a comparatively short time.

CLINICAL MEMORANDA.

REPORT OF A CASE OF GONORRHŒAL ARTHRITIS IN A NEW-BORN INFANT.

By ESTHER M. TYRRELL, M.D.,
OF CANTON, O.

DURING the writer's term of service as resident physician in the Maternity Hospital, Philadelphia, the following case occurred:

M. B., colored, aged 21 years, was brought into the hospital in labor, second stage. As there was present then a purulent discharge from the urethra, all possible precautions were taken to prevent the seemingly unavoidable contagion.

The child, a well-developed female, was born, the eyes cleansed after the most approved methods and closely watched, preventive treatment being constantly employed.

The history gotten after delivery pointed to a well-defined case of gonorrhœa of the mother, though no microscopical examination of the discharge was made to verify the diagnosis.

Four days after birth a slight puffiness of one lid, with a scarcely perceptible redness, was noticed, and by evening, though the treatment had been quickened to hourly applications, the eyes were both in an alarming condition. The consulting ophthalmologist was called, and a most vigorous battle for the eyes begun. The lids were enormously swollen, and the slightest pressure would cause the pus to spurt several inches from them.

Four days after the appearance of the ophthalmia I noticed the wrists and dorsum of both hands were slightly swollen, the left being worse. I had them bathed in a hot saline solution, but it was ineffectual, the swelling continuing until it reached from the finger tips to the elbows. The skin of the wrists and forearms was shining and edematous. The child appeared to be uncomfortable, without indication of severe pain, except for a few minutes at a time.

Applications of a 10-per-cent. preparation of ichthyol with belladonna ointment were made and the hands and arms bandaged, the bowels thoroughly opened with calomel (gr. $\frac{3}{10}$, in three doses), followed by sweet oil. Five days later the swelling had disappeared; the eyes in the mean time had yielded to treatment. At the end of three weeks the patient was discharged in good condition, though the ophthalmologist continued treatment daily at the patient's home.

In the *Medical Science Monthly* for January, 1896, is added to the as yet short list of cases of arthritis associated with purulent ophthalmia, one by Hanshalter (*Congrès de Médecine interne de Bordeaux, Revue mens. des Mal. de l'Enfance*, October, 1895).

A CASE OF COMPOUND DEPRESSED FRACTURE OF THE SKULL.

By MARTIN M. KITTELL, M.D.,
OF KINDERHOOK, N. Y.

ON the morning of Nov. 4, 1895, I was summoned to dress a scalp wound. Taking the necessary instruments and dressings I found the man seated in a mill with a cloth bound tightly around the head. An investigation developed the following history: G. W., aged 52 years; strong and healthy, was grinding knives on a small emery-wheel, with a velocity of 3000 revolutions a minute. It broke, and one section of it struck him on the right side of the forehead. He was rendered insensible by the blow for at least 5 minutes, when he regained consciousness and was able to walk into the office, where I found him about 20 minutes after the accident.

He suffered very little pain, was perfectly clear in intellect, had not been and was not nauseated. In fact, there were no symptoms of serious injury.

On removing the cloth I found a gaping wound 2 inches long, about $\frac{1}{2}$ inch wide, $\frac{3}{4}$ inch above the superciliary ridge, running slightly upward and backward. It was bleeding profusely. I sponged the part with a carbolic-acid solution, arrested hemorrhage by torsion, and found by probe and digital examination that the external plate had been driven into the diploë for 1 inch in length by $\frac{1}{4}$ of an inch in width. I carefully removed loose particles of bone and a few grains of emery; could find no exposed surface of the dura, nor could I detect pulsation. The depression seemed to be fully as deep as the thickness of an ordinary frontal bone. In the entire absence of symptoms I hastily decided to cleanse, pack lightly with iodoform gauze, and drain at most dependent part, closing all but that portion with catgut suture. After the usual dressing, he was taken home, and an ice-cap applied. I informed the family of the condition and the possible results, and mentioned to them the matter of trephining, but suggested that with the entire absence of grave symptoms I would prefer to wait until some symptom would suggest or warrant it, which was accepted. The ice-cap was worn for five days, and the wound healed by primary union. There was an entire absence of headache, irritability and fever. In twelve days the patient was at his office attending to business, and up to present writing is free of pain or mental disturbances.

I do not report this case to discourage the heroic plan of treatment in fractures of the cranium, but in the absence of symptoms it is believed that conservative methods should be recommended, rather than add the surgical shock of an operation to that already sustained.

GONORRHŒA OF THE RECTUM.[1]

By J. A. MURRAY, M.D.,
OF CLEARFIELD, PA.

ON the 25th day of March, 1895, the following unique case consulted me for treatment for what she supposed to to dysentery. She gave the following history:

Married. Age 28. Has two children. Always enjoyed good health. No uterine disease. No leucorrhea. Had always been a sufferer from constipation, for which she had, for the past six or seven years, used all the various aperients, laxatives, and cathartics. During the past two years, upon the advice of her physician, she had abandoned them all in favor of copious hot-water rectal injections, which gave her abundant relief.

[1] Read before the Clearfield County Medical Society, January 31, 1896.

For the past four or five days she had experienced great heat, pain, tension, and tenesmus of the anus and rectum, which were accompanied by a profuse discharge of blood and mucus. Complained of being very sore and irritated around the anus. There was some slight elevation of temperature, with some increase in the frequency of the pulse-rate. Urine was scanty and high colored. So nearly did the symptoms simulate those of dysentery that the treatment was directed to that disease. When the patient was seen the next day, all symptoms were increased in severity. Great pain, with constant desire to urinate and defecate. Frequent and copious injections of hot water, starch-water and laudanum were ordered in addition to rectal suppositories of opium, iodoform, and belladonna.

On the following day, which was about the seventh or eighth, counting from the time the symptoms became acute, the pain, tenesmus, and other local symptoms had not abated except when under the influence of opiates. Patient now complained of heat and pain in the vulva and vagina, with increased vesical tenesmus. Upon the development of those symptoms, it occurred to me the disease might be specific in character, and I promptly suggested a thorough examination, to which she readily consented.

The spincter ani was relaxed and there was some protrusion of the bowel. The mucous membrane of anus was highly inflamed and covered with a thick greenish mucopurulent discharge. With difficulty a small speculum was introduced, and the rectal mucous membrane was found to be intensely red and very sensitive. The labia were red and inflamed, and the nymphæ swollen, tender, and painful on pressure, although there was no vaginal discharge at this time. I suspected gonorrhœa, and to clear up the diagnosis I made some cover-glass preparations from the pus taken from the rectal and anal mucous membranes. Placing these slides under the microscope, the field was found to be loaded with gonococci, which confirmed the diagnosis of gonorrhœa. On the following day there was considerable discharge from vulva and vagina, and a microscopical examination of this pus showed it to contain the gonococci in great numbers. From this period there was superadded a typical vaginal gonorrhœa, which ran the usual course.

And now to show that this patient was not a pathic, nor her husband a pederast, I will explain the theory of the source of infection.

After confirming the diagnosis with the aid of the microscope, I explained to her the nature of the disease. Of course she was horrified, and could scarcely be made to believe such was the case, but I had fortified my diagnosis too strongly to admit a doubt. She asked me to call her husband and explain everything to him. This was done immediately, and as he had every confidence in his wife we all turned our attention to finding the cause of the disease. We suspected the servant-girl with being infected, hence her movements were carefully watched. The patient, as previously explained, was accustomed to take her daily rectal injection, which procedure was always carried out in the bathroom, where she kept her fountain syringe. It was soon discovered that the servant-girl made frequent visits to this bathroom, and each time used the same syringe. The girl was taken to task and confessed to having a well-marked attack of gonorrhœa; and naturally we concluded that the lady had infected her rectum by using this syringe shortly after being used by the girl.

When this case first came under observation all the various textbooks were consulted I could gain access to, but I found no literature on the subject, and the conclusion was reached that an important discovery had been made, which prompted the writing of this article. But, before concluding the subject, I examined an old volume of *The Annual of the Universal Medical Sciences*, and saw the subject briefly mentioned in these words, viz.: "Rollet reports one case. Gosselin one. Tardien had never seen one. Boniere has experimented and found it very difficult to inoculate the rectum with gonorrhœal pus; while Requin believes it almost sure to follow pederasty with a person suffering with the disease. Chas. B. Kelsey, the eminent rectal specialist of New York, has had occasion to suspect its presence but once." It will be perceived from the foregoing that gonorrhœa of the rectum is a very rare disease, and its existence even denied by one prominent authority. It is scarcely necessary to add in conclusion that the vaginal inflammation readily yielded to hot alkaline injections, followed by sterilized water and tamponing the vagina with cotton pledgets saturated with a solution of silver nitrate. The rectal inflammation was treated by saline purgations, copious injections of sodium-bicarbonate, and boric acid solutions, starch-water and laudanum, suppositories of opium, belladonna, sulpho-carbolate of zinc, hot poultices and fomentations. The disease of the rectum ran a protracted course and was followed by some patches of ulceration which were subsequently treated and cured by touching them with a solution of silver nitrate, followed by coating them over with stearate of zinc, and an occasional suppository of bismuth and iodoform.

SATURDAY, MARCH 7, 1896.

TO REGULATE THE PRACTICE OF MEDICINE IN THE DISTRICT OF COLUMBIA.

A bill for this purpose has passed the lower House of Congress. The Chairman of the committee having it in charge states that it is the result of more than twenty years of attempted legislation in the District of Columbia. The laws of 47 States and Territories have been presented for the use of the committee, for comparison with this measure; and for the first time in many years the different medical societies have reached an agreement as to the necessity for the passage of the bill. There is only one State in the entire Union, which has not a law regulating the practice of medicine and surgery. That is the State of New Hampshire. The District of Columbia is the only other place in the country where the practice of medicine and surgery is not regulated. The effect of the laws in other States is to drive out irregular practitioners, and many locate and practice in the District who would not be tolerated in Virginia, Maryland, or elsewhere. This bill has been carefully considered, not only by the medical societies, and by gentlemen representing the different schools of the profession, but carefully, section by section and line by line, by the Congressional committee, and all are unanimous in the opinion that a measure of this kind is absolutely necessary, and that the bill has been framed in the most fair and comprehensive manner.

BEAUTY AS AN AIM IN MEDICINE.

Do we not often take a too baldly utilitarian view of our mission as physicians? We regard ourselves as chiefly concerned with the sternly practical aspects of life, with a large number of disagreeable and repulsive disease-processes; to rid the body of which, by means often as unattractive as themselves, is our sole aim and duty. "What have we to do with beauty, in any form?" we cry; "our concern is only with health." "And health means working-capacity, efficiency, freedom from pain and disability." Nothing could be more prosaic: nothing less poetic or artistic.

But *is* this all? Have we nothing of the artist-soul about us? no enthusiasm in our work? Is there nothing in the return of health which gladdens the eye as well as the soul, the heart as well as the mind? Have we no right to rejoice in the loveliness which Nature spreads before us daily in her human masterpieces, and deliberately aim at adding to its beauty and deepening its glow by every means in our power? Most surely we have. We are painters in living colors, sculptors in breathing marble; and we can conceive no higher and purer rapture of the creative mood than that which comes to even the humblest ministrant to the welfare of the little ones as he watches the glow of health come back to the cheek, the sparkle to the eye, and the lithe, elastic roundness to the shrunken limbs under his patient and resourceful care.

Beauty is both an important guide and a legitimate aim in our practice, for in nine cases out of ten it is the "trade-mark" of health. "The flower of life is red, is red," as the poet sings. And the coloring of the healthy skin, hair, or eye is warm and vivid; while the tints of disease of every sort—of gangrene, of ulceration, of suffocation, the hues of death and decomposition—are

dull, cold, and ghastly. Filth and famine, pestilence and decay, are alike either colorless or repulsive in hue; while color is an index of purity and wholesome vigor. And this relation is even more constant and necessary in beauty of form. The chief element in beauty of outline is symmetry; and symmetry simply means balance, equipoise, efficiency, and is generally allied with either speed or strength. The second important element is the curve, and the curve essentially denotes elasticity, movement, vigor. A thoroughbred horse can almost invariably be picked out of a mob of ordinary horses, simply by the long and graceful curves of his neck, loin, and quarters and the general beauty and symmetry of his figure. Beauty of form is usually associated with great speed, strength, or intelligence, generally with all three. Among the lower animals this will be readily admitted, but that the same rule holds true of our own species, even in these over-civilized days, will be with equal promptness doubted, if not denied. And yet we venture to assert that a careful study of the elements which make for beauty in the human body as a whole and in its various parts will amply prove this position.

Take the highest form of beauty of which our bodies are capable, the grace of carriage, of bearing, the poetry of motion, and it essentially consists of and depends upon the rippling, springy vigor of muscle combined with the broad, deep chest of good lung-power, the thin flanks of endurance, the wide hips and well-rounded thighs of weight-carrying form, and the straight back held in place by the powerful bow-string of loin-muscles. The woman who possesses the most exquisite charm of a graceful bearing, the man who "carries himself well," will be found possessed of distinctly greater strength, speed, or endurance than his less attractive sisters and brothers of equal weight, age, and training.

As every rational method of pursuing beauty leads to health, ought we not frankly to recognize it as a perfectly legitimate and worthy aim in life in general and in medicine in particular; treat the desire for it as an ally, instead of an enemy? Think of the tortures which women in all ages have suffered for their idea of beauty, and then consider what a tremendous lever in managing our most troublesome cases the recognition places in our grasp! Let us encourage our patients, both male and female, to strive for beauty as well as for health, and they will attain more of both, as Heaven knows they and we need to in this latter end of the nineteenth century.

RECENT PROGRESS IN MEDICINE.

THE TREATMENT OF PERNICIOUS ANEMIA.

Whether pernicious anemia is a special disease or one secondary to a number of exhausting conditions cannot be stated with positiveness. Advocates of the one contention may urge their claims quite as logically as those of the other. Although we have been quite familiar with the histological condition of the blood, as well as with the pathological changes which go on in the hematopoietic organs, in this disease, yet no great advance had been made in the treatment of it until the publication of Professor Frazer's paper on the efficacy of bone-marrow, now nearly two years ago. In textbooks, the disease is usually stated to be a fatal one, and little hope from treatment is encouraged. The special remedial agents which are spoken of are arsenic, phosphorus and transfusion. It is also not uncommon to find it specifically stated that iron is of no value in this disease; the fact is demonstrated that it often does harm.

The drug which has been given with most confidence in the treatment of pernicious anemia, since it was first recommended by Isnord in 1865, and particularly since its claims were urged by Bramwell, several years later, is arsenic. The *rationale* of its use has never been satisfactorily explained from a physiological standpoint. Its efficaciousness in some cases is attested by trustworthy clinicians. It undoubtedly causes an increase in the number of red blood-corpuscles,—in all likelihood by stimulating the activity of the bone-marrow. But how it causes the increase in the constituents of the red blood-corpuscles—that is, in what manner the amount of hemoglobin is added to, unless it be from the food-stuffs—it is impossible to say. As a matter of fact, arsenic often provokes a temporary improvement in the patient which is coincident with this increased output of red blood-corpuscles, but which, if not followed by the administration of iron or sub-

stances rich in iron, is quickly followed by relapse that is generally fatal. There is probably no valid reason why iron in absorbable and non-irritating form should not be of corresponding value in this disease as in other forms of anemia, providing the ability to take it into the system, and dispose of it after it is so taken, exists.

Necessarily the extreme impoverishment of the blood in pernicious anemia prevents a proper secretion of the digestive juices, and rapid hemolysis results in products which stimulate thermogenesis, the result being frequently a considerable degree of fever. These two factors alone are inimical to the absorption and disposal of iron. If, however, iron can be introduced into the blood in very small quantities and in a form that does not irritate the digestive passages, there are very good reasons to believe that it is of no less service here than in other forms of anemia. It seems necessary to emphasize the statement that it does not deserve the stigma of inutility which textbooks and tradition have given to it. It is because most of the cases of this disease succumb, no matter what treatment is used, that the conviction is so widespread.

The results of transfusion, though good results have followed careful use of this form of therapy by many trustworthy observers, have never appeared very brilliant nor convincing in the published reports. Here also the *rationale* of the procedure has never been clear. One advocate will remind us that it supplies the corpuscular element, while another that it contributes necessary serum, while a third may emphasize the fact that it carries into the blood a desirable amount of hemoglobin. To each of these there may be brought very serious objections. In the first place it is the unanimous opinion of physiologists that foreign corpuscles, when introduced, it matters not how carefully, soon die and add nothing to the blood but detritus. If its benefit depends upon the serum, which is almost incredible, there is always some risk of sepsis and other complications which go far to invalidate the small amount of efficacy which this measure contributes to the treatment of the disease.

The use of phosphorus has been almost entirely given up, and very properly so.

When Frazer reported a case of pernicious anemia in which the administration of bone-marrow was causative of such good results that complete cure rapidly followed—a case in which the usual modes of treatment had been most assiduously tried, with failure—it was hoped that this disease had at last yielded to therapy. And although experience during the last two years has not served to substantiate entirely this laudable hope, one does not feel in the presence of a patient suffering from this disease to-day such complete helplessness as he did before the agent was discovered. So many clinicians, like Danforth, Drummond, Barrs, Bigger, Pepper, and Stengel, have seen such startlingly beneficial results in cases which have been apparently quite hopeless, that we can no longer withstand the feeling that this form of therapy is the most potent in the treatment of pernicious anemia. The *rationale* of its use is quite as obscure as that of those which we have previously mentioned. It is the marrow of ox and calf bones that has been used most frequently in those cases where cure has followed. In the chemical examinations that had been made of the marrow and reported, it has been found that in several cases the yellow marrow was quite as beneficial as the red bone-marrow. It is well known that the former is not like the latter a hemopoietic tissue, and the amount of iron which it contains is really almost infinitesimal—as estimated by Stockman, $\frac{1}{56}$ of a grain or less to an ounce of the marrow—while red marrow contains something more than twice that quantity, still a very small amount. Nevertheless if the clinical tests show encouraging results, as they have done frequently in the treatment of these cases, we should have the willingness to continue the treatment until physiological explanation shall follow. That this will be the outcome after a sufficient number of cases have been treated, there can scarcely be any doubt. The conflicting reports that have been made as to the efficacy of bone-marrow may be due, as has been suggested by Pepper and Stengel, to the preparation of the substance which has been used.

In the beginning the raw, unprepared marrow of ox bone was generally the form in which it was administered. Latterly a number of preparations, glycerin extract and other combinations, to palliate the patient's palate and esthesia have

been tried, and it is particularly with these combinations that failure has been reported. It would seem justifiable, after what has been done with the simple bone-marrow, to urge the necessity of making further experiments with this substance, not only in pernicious anemia, but in other forms of anemia, such as chlorosis. Indeed in the latter disease excellent results have been reported by Billings, while at the same time he mentions two cases of pernicious anemia in which bone-marrow entirely failed. Mann has likewise seen good results follow the use of bone-marrow in hemophilia, and in symptomatic anemia, and the writer has in more than one case seen surprisingly beneficial results follow its use in the latter condition. In the profound anemia attending such conditions as anchilostomiasis, in which the parasites produce a substance which causes rapid destruction of the blood and albuminous tissue, it would seem that bone-marrow should be of signal service in promoting hemogenesis—for we do not believe that it has any influence to check hemolysis—while active measures are being taken to eject the parasites from their unnatural habitation. In fact, in a case of this disease recently under observation, it would seem that bone-marrow has contributed very materially in just this way.

If pernicious anemia is a specific form of gastro-intestinal disease, a view which has for its most recent and ardent advocate Hunter (*British Medical Journal*, Feb. 8, 1896), and entirely different to anemia due to the loss of blood and exhausting conditions, for instance, no valid objection can be advanced to the use of bone-marrow in the same way as in the last-mentioned case.

The experiments of Hunter show that there are characteristic changes in the liver, spleen, and kidneys, particularly in the peripheral areas of the liver lobules, which are not produced by the absorption of extravasated blood, but are in direct relationship with the gastro-intestinal tract, wherein the hemolysis begins which is responsible for the pigment. These experiments have been done in such a scientific manner, and the conclusions have been stated in such a logical way, that they carry conviction. They do not, however, suggest a way in which treatment may be more efficacious; for though they may prompt the suggestion that the gastro-intestinal disease is due to some organism, we know practically that treatment of pernicious anemia directed to that end is useless, or nearly so.

Joseph Collins, M.D.

ECHOES AND NEWS.

Long Branch, N. J., is to have a public hospital for contagious diseases.

A bill has just received the signature of Gov. Morton, of New York State, appropriating $6000 for equipping the quarantine boat *Ripple* used in New York harbor, with disinfecting apparatus. It is hoped that this will somewhat improve the very primitive methods formerly used.

Mrs. William Allen, of Pilot View, Ky., celebrated her eightieth birthday the other day by completing the cutting of her third full set of teeth.

A resident of Springfield, Mass., who made the pilgrimage to Denver and was "cured" of a chronic disease by the healer Schlatter, died in a hospital last week as the result of an operation which was made necessary through neglect of ordinary treatment during the time his faith lasted.

Dr. Edward Everitt, of Newark, N. J., died at his home, of malignant diphtheria, supposed to have been contracted in attending two children afflicted with that disease.

The insignia for the Medical Corps of the United States Army have been finally decided upon. It is a modified cross of the Knights Hospitaller—a Greek cross. This is to be seven-eighths of an inch high and the same in width, and to be of dead gold bullion or metal.

Dr. T. T. Thomas, resident physician at Charity Hospital, Norristown, Pa., has been elected to a similar position at the University Hospital, Philadelphia.

Sir James Crichton Brown, the eminent English surgeon, has given the name "anorexia scholastica" to a certain brain trouble which afflicts those young women who "read Lucretius for recreation and cannot boil a potato." Although in itself not a dangerous disease, the sequences may prove serious.

Dr. Floto, of San Francisco, who is 94 years old, is still in the active practice of his profession. He believes that he is the oldest practicing physician in the country.

A London investigator, Mr. J. G. Vine, announces that he has been able to photograph, at one end of a wire, objects exposed between two vacuum tubes at the other end of the wire, and declares that he will soon be able to photograph objects at any distance by means of X or magnetic rays conveyed by wire.

Dr. A. L. Metz has been elected to succeed temporarily the late Prof. Joseph Jones as professor of chemistry and medical jurisprudence in Tulane University, New Orleans, La.

Mr. G. D. Pratt, of Brooklyn, N. Y., has given to the trustees of Amherst College a sum of money sufficient for the building of an infirmary for the use of sick undergraduate students. The work of excavation will begin in the early spring.

A hot spring is reported to have broken forth near No. 326 East Houston street, New York city, which has already acquired great fame among the denizens of the East Side, on account of its curative properties. Surely it could not have selected a more convenient locality at which to deliver its stream "for the healing of the nations," for they are all represented in that vicinity.

The Baltimore Medical Association held its regular annual meeting on the evening of February 24th, and elected the following officers for the ensuing year: Dr. Randolph Winslow, president; Dr. Herbert Harlan and Dr. Joseph T. Smith, vice-presidents; Dr. W. E. Wiegand, corresponding secretary; Dr. Eugene Crutchfield, recording secretary; Dr. C. Urban Smith, treasurer; Drs. H. H. Beidler, E. G. Waters, and John Neff, Executive Committee; Drs. Wilbur Brinton, S. T. Earle and John W. Chambers, Committee of Honor.

One hundred and fifty cases and fifty deaths from yellow fever are reported to have occurred on board the Italian cruiser *Lombardia*, which is now in the harbor at Rio Janeiro, Brazil. Alertness will be required by the quarantine of the Atlantic and Gulf ports to prevent the entrance here of this dread scourge.

All the police force of Lansing, Mich., were in quarantine several days last week, and the police station and town jail were closed during the same period, while the policemen were vaccinated. A tramp with smallpox came to the police station and was passed on to the jail. Practically every member of the force came into contact with the man, and so the force was put in quarantine, and the jail and station-house were closed and disinfected.

It is reported from Elgin, Ill., that the dairymen of that section are considerably alarmed at the statement of Dr. Trumbower, State Veterinarian, that in his opinion 50 per cent. of the dairy cattle thereabout are afflicted with tuberculosis. Of thirty-three cattle belonging to the State Insane-asylum which were submitted to the tuberculin test, fifteen were condemned, and all of them were fat, sleek, and apparently healthy. Five of those pronounced diseased were slaughtered, and tuberculosis was found to exist in a pronounced degree in all. Abscesses as large as a man's hand were found in the lungs, and the lymphatic glands and the lungs were thoroughly permeated with tuberculosis.

Steel-coated rifle bullets for the new magazine guns cause very little pain, says Dr. Delorme, surgeon-in-chief of the French Army. During the riots at Fourmies, France, one man was wounded so badly as to be paralyzed, but did not suspect that he had been shot until he saw blood-stains on his clothing; one, shot through the leg, only felt a slight shiver; another, shot through the arm, felt his elbow twitch and closed his fist mechanically. At short range, 100 to 150 yards, the bullets are apt to explode and do serious mischief.

At the regular monthly meeting of the New York State Board of Health, held at the Hotel Métropole, New York city, February 28th, Dr. F. O. Donohue, the chairman of the Committee on Tuberculosis, presented an exhaustive report on the work accomplished in the way of destroying diseased animals since July 15, 1895. The report states that 527 bovines suffering from tuberculosis were destroyed since the date named; that $12,282.25 have been paid out in awards to the owners of the cattle. The greatest slaughtering of diseased cattle was done in Dutchess county, but many animals were also destroyed in Westchester and Putnam counties. The appropriation last year for the work of the committee was $30,000, but Dr. Donohue says this sum is not enough. The secretary's report stated that there were 900 fewer human deaths in January, 1896, than in January, 1895, and fewer than in the four years preceding. "There was an increase," the report says, "in the mortality from typhoid fever, scarlet fever and measles, and diarrheal disease. There were nearly 600 fewer deaths from acute respiratory diseases and 100 fewer from consumption and nervous diseases." Dr. S. Case Jones submitted a report on the typhoid-fever epidemic in Elmira. There were, between January 3 and 27, 87 cases of typhoid fever reported in Elmira. Seventy-seven cases were in families using the city water for domestic purposes, and the remaining 10 cases were among children who used the city water in the schools. Dr. Jones said that the State Board of Health should enforce the law to prevent the pollution of rivers by sewers, and that the authorities of Elmira should insist that the drinking-water from the Chemung River should be filtered before distribution.

Experiments made with electricity on the toxins of disease by MM. d'Arsonval and Charrin, of Paris, France, show that the effect is to attenuate the toxin, converting it into a useful antidote. The toxin of the diphtheritic and the pyocyanic bacilli was subjected to the physical action of currents of high frequency. The current had no direct influence on the vitality of the microbes themselves, but modified the liquid in which they live so as to render it noxious to them. The action of the current, it is asserted, is not chemical, but purely physical. In twenty minutes a virulent poison can be turned into vaccinating matter. Electricity is to be tried on animals infected with the toxins, to see whether the effect is the same on living tissue.

Experiments on the spreading of disease by burial, made by Dr. Loseuer, of Paris, France, tend to prove that there is little danger of infection from the practice. Carcasses of animals infected with different diseases were

buried as nearly as possible as human bodies would have been. Bacilli of cholera could no longer be found in the remains after 28 days, those of typhoid fever disappeared after 96 days, those of tuberculosis after 123 days, those of tetanus were very virulent after 234 days, but disappeared after 361 days, while the anthrax bacilli continued in full force to the end of the year of investigation. In none of these diseases, save that of anthrax, did the germs find their way to the surrounding soil and water.

The work of the Section on Neurology and Medical Jurisprudence at the coming meeting of the American Medical Association at Atlanta promises to be of unusual interest. The desire has been quite generally expressed to have discussions upon the following topics: The Etiology of Insanity; Expert Medical Testimony in Disputed Mental Cases; Medical Aspects of Crime. An urgent invitation is extended to present papers and records of cases that have a bearing upon these topics, or upon any other neurological or medico-legal subject. Those who expect to contribute papers or reports to this section will greatly facilitate the business of the section by writing at once to the chairman, T. D. Crothers, M.D., Hartford, Conn., or to the secretary, W. J. Herdman, M.D., Ann Arbor, Mich.

The Section on Surgery at the next meeting of the American Medical Association at Atlanta, Ga., will devote special attention to "Surgery of the Cerebro-Spinal Axis and its Bony Encasements." It is urgently requested that all members who have papers or other material bearing, not only upon this, but any subject coming properly within the province of this section, will correspond with Dr. W. L. Estes, secretary, South Bethlehem, Pa., at an early date, giving title and other particulars concerning their proposed contributions.

SOCIETY PROCEEDINGS.

REPORT OF THE LOUISVILLE CLINICAL SOCIETY.

Dr. W. H. Wathen presented reports of the following cases:

PYOSALPINX WITH OVARIAN ABSCESS.

Case 1.—Two years ago a single woman, aged 22 years, consulted me for severe pain in the region of the ovaries and tubes. Examination revealed a fixed uterus with a tumor upon each side connected with the ovaries or tubes. She had been suffering for a considerable time, and gave the history of having been infected with gonorrhœa. Diagnosis of pus-tubes was made and operation recommended.

She passed from my observation and I saw nothing more of her for two years. Recently she was again referred to me by another physician. She reported that after being treated by me she improved very much and thought she was well, occasionally suffering, but had been for the past few weeks suffering very severely in the pelvis, had a constant elevation of temperature of from one to three degrees, with acceleration of pulse. In an examination I found more immobility of the uterus and more extensive involvement of both sides.

She was operated upon, and the tubes found in Douglas' pouch firmly adherent. They were brought up and the tubes and ovaries removed. There is one interesting point to which I wish to call attention. When the adhesions upon the left side, where the largest tumor was situated, were separated, something that appeared to be pus came up into the wound and was wiped away. When the tube and ovary were removed it was found that this was pus and that it came from the ovary, which was full of *foci* of pus, giving it the appearance of a sponge filled with pus. Upon a careful examination of the specimen, it was found that the ovary had become infected, not from the end of the tube, as is usual, but from about the junction of the inner with the middle third, where a very small opening connected the tube with this sponge-like ovary. As the abdominal cavity was not irrigated, I was a little fearful some pus from the ovary might have remained, though I sponged everything away very carefully; but the woman made an uninterrupted recovery.

PYOSALPINX ON LEFT SIDE, WITH TUBE AND OVARY ON RIGHT SIDE HEALTHY.

Case 2.—Patient aged 25 years recently consulted me and was operated upon a few days later. She had been suffering a great deal for the last few weeks, or months possibly, with pain in the region of the ovaries, uterus, and tubes. On one side a very considerable enlargement was found; on the other side the enlargement was not so great. The abdomen was opened and the tubes found to be firmly adherent. One side was badly diseased with a pus-tube, which was removed; on the other side, although the adhesions were equally as extensive, the tube was found to contain no pus, and the ovary normal, so they were not removed, and the woman may bear children.

ANTERIOR VENTRAL FIXATION AFTER REMOVAL OF A SUBPERITONEAL PEDUNCULATED MYOMA.

Case 3.—Operated upon to-day, neither ovaries nor tubes were removed. The patient was referred to me a few days ago, diagnosis of pyosalpinx having been made. The uterus was fixed in a retroverted position and the ovaries and tubes were adherent in Douglas' pouch. It was impossible to say whether the tubes contained pus or not, but it was easy to see that the woman was suffering with peritionitis and that an operation ought to be performed. When the abdomen was opened the adhesions were found extensive, binding the uterus, ovaries, and tubes, but were not difficult of separation, and the tubes and ovaries were found to be nearly healthy. A small fibroid tumor about one inch in diameter was removed from the fundus of the uterus. The uterus was sutured to the anterior abdominal wall by two silk sutures introduced through the peritoneum on each side and through the sides of the uterus near the fundus, and tied between the peritoneum and the muscle, so that they were buried when the abdomen was closed. Another suture was introduced through the fundus of the uterus and brought out through the abdominal walls and tied over the abdominal wound just as any other suture that closes the abdominal incision.

This woman, I think, will be entirely relieved and be able to bear children.

DISCUSSION.

Dr. W. C. Dugan: What do you think was the cause of the pelvic peritonitis?

Dr. Wathen: I think it was the result of an abortion, because from the history she gave me I infer that she had an abortion some months ago; the septic matter did not pass, I am sure, through the tubes, but must have gone through the lymphatics to the peritoneal structures.

Dr. Dugan: I do not fear pus-tubes as I formerly did, nor as I do pus from an appendicular abscess. I think the pus is often innocuous, and when left in the cavity will not cause any trouble. I am not surprised at all that Dr. Wathen had no peritonitis following the operation where pus escaped into the cavity, for it is well known that if pus, at first of a very virulent form, has been retained for a long time, the pus-forming organisms will die and the pus become innocuous. This undoubtedly explains why we do not have peritonitis following the escape of pus into the peritoneal cavity, and I think the Germans are right in not subjecting these patients to irrigation, that used to be so common with operators in this country. The time was when this patient would have been flooded with gallons of water; and where we subject these patients to so much irrigation there is very apt to be more or less septic matter introduced in the same way, and the patients do not do as well as when treated as Dr. Wathen has described. The pus contained in pus-tubes is not, as a rule, virulent; and careful sponging in such cases is better than irrigation.

Dr. T. P. Satterwhite: What are the statistics with regard to stitching the uterus to the abdominal walls for the cure of retroversion? Furthermore, if it is successful, would this not also relieve procidentia?

Dr. Wathen: The operation for ventral fixation of the uterus, if performed correctly, should be almost without exception primarily successful. There is no reason why it should not be, and it is practically devoid of danger. Further, the uterus will remain, in nearly every instance, permanently fixed. Dr. Howard Kelly, of Baltimore, who has probably done more of this work than any other operator, shows that many women have become pregnant after ventral fixation, have carried the children to term, and have been relieved afterward, the uterus ascending properly, and, when involution had been completed, remaining in its anterior position.

Ventral fixation is an excellent means of curing patients having procidentia, if the uterus is not too large. In these cases it is best to amputate the neck of the womb as high as we can; and if the vagina is much dilated, with a cystocele or a rectocele, or both, anterior ventral fixation should be preceded by an operation upon the vaginal wall that will narrow it and bring it nearly to the normal size.

In doing an operation for anterior ventral fixation I always scarify the uterus and the peritoneum that comes in contact with the uterus, to insure more perfect adhesion. I think scarification is advisable in all cases, though cases have been reported where union was firm without it. I have failed to secure adhesion in one case, which I attributed to the fact that I did not properly scarify the surfaces.

Dr. Louis Frank: Take, for instance, the patient operated upon to-day. If this woman subsequently becomes pregnant, what will become of the suture, and what effect will the suture have upon the course of the pregnancy?

Dr. Wathen: There should be no effect upon pregnancy; what becomes of the suture I do not know—it may be absorbed, or it may remain intact. When the uterus ascends it must carry the adherent peritoneum along with it to a certain extent, and, this being true, the fact that the suture is buried in the peritoneum and the uterus, it would not be disturbed in its relation to these two structures. Experience, however, has shown that these buried silk sutures do no harm. I would prefer to have a buried silk suture to a buried silkworm-gut suture in the event the woman became pregnant.

Dr. Frank: I want to say a few words as to ventral fixation for the cure of retroversion, with the occurrence of subsequent pregnancy and after results in these cases. I have read with a great deal of interest, especially since the last discussion upon ventral fixation before this society, all the literature upon the subject. Dr. Howard Kelly's statistics I have not seen. So far I have been able to find the report of but one case, I think by Edebohls, where pregnancy has occurred after the operation of ventral fixation, the uterus subsequently returning to its natural position.

The after result in these cases, I think, is of the greatest importance. It strikes me that these adhesions between the visceral and parietal peritoneum must become stretched as a result of pregnancy; then with the occurrence of subinvolution at any future time the uterus would necessarily go back to its retroverted position. The trouble is that the original cause of the displacement is still present. What results Dr. Kelly has obtained in this connection I do not know. Edebohls' case, which was exhibited, did not show any relapse. This case was certainly cured.

There is no question but ventral fixation, as well as a properly adjusted pessary, will mechanically cure retroversion by fixing the uterus in a position where it cannot again fall back. In both, however, the cause of the retroversion is not removed, so that if there is any stretching, which sooner or later in pregnancy, it seems to me, must occur to some extent, then during involution the uterus would fall back. They are not cures, in the proper sense.

As to the buried suture: I can hardly agree with Dr. Wathen that these sutures when put in this way will remain in place. It strikes me that they must pull out. The parietal peritoneum does not during pregnancy ascend along the anterior abdominal wall as the uterus ascends; and when the uterus rises, as it does, above the umbilicus, the sutures must pull out, or the adhesions be torn. This, it impresses me, must be the ultimate result, unless the sutures pass from the lower portion of the body of the uterus instead of from the fundus or sides of the organ.

As to ventral fixation for the cure of prolapsus of the uterus, I agree that if there is a prolapse of the vagina, this must be cured first. There is frequently a laceration of the perineum resulting in a retrocele, and also a cysto-

cele with this prolapsus uteri, which must be cured, and the lacerated surfaces also remedied. The condition in such a case is very much like any other hernia, it being in fact a pelvic hernia, and would necessarily be the most difficult of all to cure by ventral fixation. I think intra-abdominal pressure, the cause primarily of the operation, must necessarily sooner or later, if we rely exclusively upon ventral fixation, force the uterus down where it was before.

The operation recommended by Freund holds the uterus in position very well; I do not believe, however, that it is a desirable operative procedure. It certainly cannot be successfully done in women who expect to bear children. I would like for Dr. Wathen to bring out these points a little more fully.

Dr. Wathen: In prolapsus uteri we almost invariably find, as Dr. Frank has suggested, either a partial rupture of the perineum, or a perineum that has lost its resisting power because of pressure; and in addition to this a prolapse of the anterior or posterior vaginal wall, or of both. The vaginal tissues are generally thickened, so that this additional weight helps to maintain the procidentia. The uterus in nearly every case is much enlarged and elongated; only recently I measured a uterus that was freely prolapsed, and found it six inches in length. In a case of this kind if we simply perform ventral fixation, with no support from below, we will find that the adhesion will gradually give away and the uterus with the vaginal wall will again become prolapsed. But if we operate upon the perineum and vaginal wall, and neck of the uterus if indicated, then perform at the same sitting, or on a subsequent occasion, ventral fixation, we will cure nearly all of these patients. I have cured a great many cases of complete prolapsus by amputating the neck of the womb, and by removing a portion of the vaginal wall (either anterior or posterior), or by removing both posteriorly and anteriorly a portion of the vaginal wall. I operated upon a woman by this method several years ago, two months after birth of a child, removing a section of the vaginal wall posteriorly and anteriorly. The patient had a protrusion as large as two fists. She has had no recurrence of the trouble. So I say that many cases of complete prolapsus may be cured by perineal and vaginal operations, supplemented by amputation of the neck of the womb.

Dr. Dugan: The question raised by Dr. Frank does not seem to have been answered by Dr. Wathen—*i.e.*, Does the uterus go back to its retroverted position after pregnancy? It has been known that, in a woman having a retroverted uterus, becoming pregnant and being delivered at term, the uterus permanently returned to its normal position. This is easily understood.

Dr. Satterwhite: I may have misunderstood Dr. Wathen's description of a lacerated or deficient perineum as being one of the causes of procidentia. If this be true, then I would like to know how to account for many cases of prolapse where the perineum is intact. If the perineum is intact then it certainly should withstand the pressure from above and prevent the uterus coming out. I do not see that the perineum has one iota to do with preventing or causing prolapse of the uterus; it is the ligaments of the uterus and reflexion of the peritoneum that hold the uterus in its normal position; and if the ligaments are capable of being stretched to allow the uterus to ascend as it does during pregnancy, I do not see why it may not also descend sufficiently to allow complete procidentia regardless of the resisting power of the perineum. I remember this subject came up many years ago in a meeting of this society, and, from my anatomical knowledge of the subject, I took the same ground then—that the perineum had little to do with supporting the uterus. Dr. Gill Wylie in a published article takes the same view.

Dr. Wathen: In cases where the uterus, vagina, and all the generative organs are in a healthy condition, I would say the perineum has nothing *directly* to do with supporting the uterus. But where there is a rupture of the perineum, associated with rupture of the superficial, middle, and deep layers of fascia, the support that holds the anterior vaginal wall intact is destroyed, and the rectum falls forward, resulting very soon in a rectocele that forces down the posterior vaginal wall, causing it to dilate more and more and become thickened and lose its tonicity; so that instead of the vagina furnishing support to the uterus, as it certainly does in a healthy condition, it does by its weight tend to pull down the uterus, gradually retroverting it and finally causing prolapse. When the perineum and fascia are destroyed, the vagina is put in such a condition that it does not return to its normal dimensions, and gives no support to the uterus; in fact it tends to draw the uterus down; but with the perineum intact, and the vagina in a healthy condition, being held posteriorly against the rectum, anteriorly against the bladder, and latterly attached to the pelvic structures, it does not aid materially in holding the uterus in its normal position, which is conducive to complete involution of the uterus and broad ligaments.

For these reasons it is necessary, in all cases where the perineum has been torn, to repair it in cases of procidentia; but the restoration of the perineum will do practically no good unless we restore abnormal to normal conditions.

OBITUARY.

Dr. Nelson Fanning, Sr., who died at his home in Catskill, N. Y., Thursday, February 27th, was one of the oldest physicians in the United States. He was in active practice until within a few days of his 88th birthday, and had been continuously a medical practitioner for 66 years. In the war of rebellion he served nearly two years as surgeon of the 134th New York Volunteers.

Dr. Smith Ely, for many years a leading physician and surgeon in Newburg, N. Y., died February 28th, of heart disease. He was 68 years old. He studied medicine in New York, London, and Paris, and was graduated from the Vermont Medical College.

Dr. Laughton McFarlane, professor of surgery at the Toronto University, died February 29th, of blood-poisoning, contracted while amputating the toes of a patient at the General Hospital a week previous. He was 54 years of age.

ORIGINAL ARTICLES.

THE INDICATIONS FOR ALEXANDER'S OPERATION.[1]

BY DR. PAUL F. MUNDÉ,
OF NEW YORK.

SINCE I performed my first Alexander's operation, on December 12, 1884—the first, I believe, done in this country—I have so often had occasion to express my views on this operation and to mention my growing experiences with it, that I scarcely feel that I can now add anything new to what I have already said and written on the subject. My riper experience, which now comprises 97 cases, confirms my previous observations and makes me a stronger believer than ever in the value of Alexander's operation for properly selected cases. What these cases are—that is, what are the proper indications for the operation?—seems to me perfectly clear. The indications are based on clearly drawn lines and are substantially the same as those originally formulated by Alexander. Briefly stated, they are the following:

1. Retroversion or retroflexion of the uterus of long standing where pessaries either do not maintain the uterus in position, are not retained, or cause pain.

2. Retroversion or retroflexion of long standing, associated with relaxation of the uterine supports (ligaments, pelvic floor, and vaginal walls) and consequent greater or lesser *descensus uteri*.

3. *Prolapsus uteri et vaginæ* where the Alexander's operation is preceded at the same sitting by trachelorrhaphy or amputation of the cervix, and is followed by anterior and posterior colporrhaphy and perineorrhaphy.

4. The desire of the patient to be *cured* of her displacement, a wish which no pessary or other non-operative treatment can fulfil.

5. The necessity for keeping the uterus in its normal anteverted and elevated position after the adherent fundus uteri and appendages have been loosened and restored to their normal mobility, either by bimanual tearing of the adhesions or by peeling the organs loose with the fingers through an incision in the posterior vaginal pouch and Douglas' cul-de-sac.

[1] Read before the Section on Obstetrics and Gynecology, New York Academy of Medicine, February 27, 1896.

If the adhesions are broken without opening the cul-de-sac the uterus and appendages *may* be kept in the normal position and prevented from again becoming adherent by a sharply curved lever pessary. But when the cul-de-sac has been opened, only Alexander's operation, or one of the other surgical procedures by which the fundus uteri is kept elevated or anteverted, is practicable. Packing the posterior vaginal pouch with gauze would scarcely suffice to attain this object.

The *counter-indications* for Alexander's operation are:

1. Adhesion of the uterus or appendages.

This is an absolute and positive counter-indication for Alexander's operation.

2. The possibility of retaining the uterus and appendages in a normal position and of making the patient perfectly comfortable with a pessary, unless, of course, the patient insists on a *cure*, as already mentioned.

3. *Prolapsus uteri et vaginæ* of the second or third degree—that is, with the cervix down to or out of the vaginal orifice—unless the plastic operations referred to (anterior and posterior colporrhaphy and perineorrhaphy, and reduction of the weight of the uterus by trachelorrhaphy or amputation of the cervix) are performed at the same sitting. It is asking too much of the round ligaments to expect them to support the weight and traction of a large uterus and the vaginal walls, with bladder and rectum, without assistance from the inferior supports of these organs.

There is one objection to Alexander's operation, and that is, not the difficulty of finding the ligaments—for with the possible *very* rare exception of their absence (if, indeed, that occurs at all) or of their not following the usual course, they can *always* be found—but the impossibility of knowing beforehand whether the ligaments will be strong enough to be of actual service in suspending the uterus. That is a chance we have to take. There certainly are a number of cases (scarcely ten per cent., in my experience) where the ligaments are not much thicker than a large knitting-needle, and break when strong traction is made on them, or are too thin to be of much use. This is the only objection I know against Alexander's operation. The mortality, in

my hands, has been *nil*. I have seen no hernia occur in the scar; only once temporary irritable bladder, and no other evil results.

A number of my cases have borne children afterward, some several, and the uterus has retained its normal position. In two cases of prolapsus (a bad indication) and in one of retroflexion the displacement returned, each time after childbirth. I have been informed of several of my cases which were seen by other physicians, where the retroversion had returned, and one case of inguinal hernia has been reported to me. But I think I am safe in claiming that of my 97 operations (several of which are still too recent to warrant conclusions) 87 were permanently cured.

I prefer Alexander's operation to ventral fixation: because it is safer (at least I claim that opening the peritoneal cavity can never be *entirely* free from danger); because it is more logical and rational to substitute a normal position of the uterus for an abnormal one, that by again putting that organ in an unnatural position as is done by sewing the fundus to the anterior abdominal wall; because shortening the round ligaments does not interfere with the progress of gestation, as I have known to be the case after ventral fixation in one of my 12 cases of the latter operation; and finally because, after ventral fixation, if the abdominal walls are thin and relaxed they are drawn inward and downward by the steady traction of the uterus, and the displacement returns. This remark applies chiefly to cases of prolapsus.

I am opposed on theoretical grounds to Mackenrodt's vaginal fixation, because it substitutes for a movable retroflexed uterus an immovable anteflexed one. However, I have of late heard of good results from this operation in the hands of an entirely unbiased surgeon, and may be convinced in time that it is not as illogical as it has appeared to me to be.

In Germany, the birthplace of this operation, its popularity seems already to be on the wane. Leopold, of Dresden, on Dec. 9, 1895 (*Centralbl. für Gyn.*, Feb. 8, 1896), pronounces against it in favor of ventral fixation on very much the same grounds on which I base my disapproval; and in the same number of the *Centralblatt* I find an article by Rühl, of Eibach-Dillenburg (a to me unknown, but certainly rural, locality), who boasts of 235 Mackenrodt operations (*sic*, in a country practice), but feels, in candor, compelled to report: five cases of dystocia following the operation performed by himself; three of difficult version; one of perforation, and one of forceps, the two last only after incising the anterior lower segment of the anteverted uterus, both children being dead. In all cases the extreme anteversion of the uterus, and the difficulty in reaching the external os in the sacral excavation, together with a firm cicatricial ring in the anterior segment of the uterus, were the causes of dystocia. Besides, Strassmann and Graefe each report a case of cesarian section, after Mackenrodt's operation, made necessary in consequence of the above-mentioned obstacles to delivery.

I do not think that any such objections can be advanced against Alexander's operation, or even against ventral fixation.

THE INDICATIONS FOR VENTRAL FIXATION OF THE UTERUS.[1]

By GEORGE M. EDEBOHLS, A.M., M.D.,
PROFESSOR OF DISEASES OF WOMEN, NEW YORK POST-GRADUATE SCHOOL; GYNECOLOGIST, ST. FRANCIS HOSPITAL; CONSULTING GYNECOLOGIST, ST. JOHN'S HOSPITAL.

Recent literature, or, more correctly speaking, events reported in the recent literature, have greatly modified the indications for the several retroversion operations. The discussion of the relative merits of these operations must now be carried to a higher plane than that of mere technique and of immediate and remote anatomical results. Their greater or less interference with the functions proper of the uterus, child-bearing and childbirth, constitutes the higher standard by which they must be judged.

Let us first, then, review the evidence now in as regards pregnancies following vaginæ-fixura uteri, ventri-fixura uteri, and shortening of the round ligaments, the three operations under discussion this evening.

1. *Pregnancy following vaginal fixation of the uterus.*—Strassmann[2] has recorded the following disturbances of pregnancy: (*a*) Disorders and pain in the vaginal cicatrix (Dührssen, 6 cases). (*b*) Abortions; 25 per cent. at least in Dührssen's cases; over 27 per cent. in his own. (*c*) Vesical pain and disturbances of micturition. The literature of the past few months records the following serious complications and disasters of parturition: 1. (Strassmann.[3]) Transverse presentation; prolapse of funis; very difficult version due to abnormal conditions established by vaginal fixation; severe post-partum hemorrhage; rupture at site of cicatrix. 2. (Strassmann.[4]) Delivery per

[1] Read before the Section on Obstetrics and Gynecology, New York Academy of Medicine, February 27, 1896.
[2] *Ges. f. Geb. u. Gyn. zu Berlin*, Oct. 25, 1895.
[3] *Ibid.*
[4] *Ibid.*

vaginam impossible; cervix above promontory of sacrum and pointing upward; Porro operation; rupture of vagina; death from intraperitoneal hemorrhage 1½ hours after operation. 3. (Graefe.[1]) Transverse presentation; cervix above pelvic brim and directed upward; version impossible; cesarian section. 4. (Wertheim.[2]) Version rendered necessary, as well as exceedingly difficult and dangerous, by same conditions as in Strassmann's and Graefe's cases. 5. Rühl[3] reports 235 vaginal fixations performed by himself, with 12 subsequent pregnancies. In three of these the vaginal fixation necessitated version, which was performed successfully for mother and child. The remaining two required bloody incision of the vaginal cicatrix, and one of them craniotomy in addition, before delivery could be effected, the second child also being lost.

The three things common to all of the above cases were: the abnormal position of the cervix above the pelvic brim and pointing upward, the undue expansion and dangerous thinning of the posterior uterine wall, and the firm fixation of the immensely hypertrophied anterior wall in the pelvis, the latter condition constituting the obstacle to delivery. These conditions are all, beyond question, chargeable to the vaginal fixation: I have purposely refrained from citing other disturbances of pregnancy attributed to vaginal fixation, the interpretation of which might be open to doubt. In the discussion following the reading of Strassmann's paper other cases of serious disturbances of pregnancy and parturition were brought to light, and anxiety was expressed for the ultimate fate of the already numerous victims of the yet young operation. Bockelmann estimated that there were in Berlin alone about one thousand women with the dire possibilities of vaginæ-fixura gestation and delivery ahead of them. In New York there are perhaps two hundred such unfortunates. Who will dare to add to their number? With the evidence now in, I would neither perform, nor sanction in consultation, vaginal fixation *in a woman liable to future pregnancies*, with one possible exception only, to be mentioned later. Dr. Vineberg, in a paper on "Conservative Surgery upon the Uterus and Adnexa by the Vaginal Route," read a few evenings ago, cited 42 cases in point, in 34 of which he performed vaginal fixation in retreating from his conservative attack upon the uterus, tubes, and ovaries. In view of recent developments regarding vaginæ-fixura pregnancies shall we hope, or shall we not, that the conserved organs will functionate in these 34 cases? A literature on the pathology and treatment of vaginal-fixation pregnancies has already sprung up (Strassmann, Wertheim, Rühl).

Mackenrodt, the originator, or, perhaps more correctly, one of the originators and chief champions, of vaginal fixation, has formally disowned the operation, for the reasons just recorded. Unfortunately he has already adopted another unpromising child, *vesico-fixura uteri*. The only novelty about the latter operation is that Mackenrodt, and Staude before him, performed it per vaginam, while Werth in 1894, Pryor,[1] and more recently Westphalen, and perhaps others, have operated from above.

2. *Pregnancy following ventral fixation of the uterus.* — Milaender[2] has collected 54 confinements at term after ventral fixation, with 11 difficult labors—4 forceps, 2 cesarian sections, 2 podalic versions, 2 transverse presentations, 1 foot presentation. Of the whole number of pregnancies after ventral fixation, 74, collected by Milaender, 6 terminated in abortion, 3 by premature delivery, 10 were still pregnant at time of report, and 1 died. The death, however (one of my own cases), which was due to long standing valvular heart disease, occurred suddenly on the eve of confinement, and had absolutely nothing to do with the ventral fixation. Strassmann[3] reports two further cases of difficult labor after ventral fixation. Norris[4] reports a case in which the thickened uterine wall at the site of the ventral fixation proved an obstacle to delivery, rendering necessary cephalic version, with high Tarnier forceps, and resulting in the death of the child. Noble[5] asks for a collective investigation, stating that he has had some recent unfortunate experience concerning the influence of ventral fixation upon parturition.[6] My personal experience is negative as regards disturbances and difficulties of pregnancy and parturition following, *and the result of*, ventral fixation of the uterus. I have performed the operation 73 times. In 34 of these cases both ovaries and tubes were removed, 6 were unmarried, 7 over 40 years of age, leaving 26 patients more or less liable to pregnancy. Eight of these 26 have become pregnant with the following re-

[6] In the discussion following the reading of this paper, Dr. Noble stated that in a case of pregnancy after ventral fixation he was obliged to do a Porro during labor at term, being unable to deliver *per vias naturales*. The woman died from sepsis antedating the Porro operation.

sults: One produced a miscarriage upon herself at the second month; one died of heart disease on the eve of confinement.[1] A third case died near term, septic from retention of a dead fetus aged 7 or 8 months. Drs. Hanks and Coe, under whose care the patient was delivered, inform me that her condition and death bore absolutely no relation to the previous ventral fixation. Five of the 8 cases, finally, were safely and easily delivered of living children at term, one of them by forceps. All were head presentations. The abortion and the two deaths in my cases are not attributable in any way to the preceding ventral fixation. Certain anomalies, however, have been common to all of my own cases and to many reported by others, of pregnancy following ventral fixation. I refer to the thickening of the uterine wall at the site of fixation, and the ballooning or compensatory dilatation of the posterior uterine wall. In a general way it may be said that, in pregnancy following ventral fixation, that part of the uterine wall anterior to and below the point of fixation thickens, while that part posterior to and above that point dilates, with the growth of the product of conception. The liability to abortion and disturbances of pregnancy and parturition after ventral fixation depends, theoretically at least, a great deal upon the particular technique adopted. The recent modification of the operation adopted by Kelly, who stitches the posterior uterine to the anterior abdominal wall, seems particularly illogical and unfortunate in this respect.

3. *Pregnancy after shortening of the round ligaments.*—A slight drawing pain beginning with the eighth month of pregnancy, and attributed, whether correctly or not, to traction upon the shortened ligaments, has been noted in a few cases. Beyond this, disturbances of pregnancy or parturition, *due in any way to the operation*, have not been observed in the numerous instances of conception following shortening of the round ligaments.

Applying to each of the three operations the crucial test of interference with the normal course of subsequent pregnancies, then, in accordance with the evidence above submitted, vaginal fixation must be discarded altogether in women liable to future pregnancies, ventral fixation must be viewed with strong distrust, while the results of shortening of the round ligaments will alone bear close scrutiny. I have dwelt thus long upon this, which to my mind is *the* important aspect of the question, as it leads logically and unavoidably to two principles or propositions which cover a great part of the subject before us for discussion this evening:

1. Vaginal fixation of the uterus should never be performed *upon a woman liable to future pregnancies*, under any conditions, when ventral fixation or shortening of the round ligaments will meet the indications just as well or better. Personally, I have been guilty of only one vaginal fixation. This was performed upon a young girl suffering from adherent retroversion of the uterus, with normal tubes and ovaries. Ventral fixation was attempted, after separating the adhesions, and failed, as the fundus could not be brought up to the anterior abdominal wall, on account of firm fixation of the cervix by parametritis posterior. I closed the median incision and immediately shortened the round ligaments, hoping that measure would suffice to keep the fundus forward. A pneumococcus infection of both inguinal wounds caused both ligaments to slough and the uterus again fell backward. A few months later I performed vaginal fixation, with the result of relieving my patient of her symptoms, and of keeping the uterus, if not in ideal anteversion, at least in front of the promontory of the sacrum.

2. Neither vaginal fixation nor ventral fixation should be performed *upon a woman liable to future pregnancies*, for the cure of an uncomplicated retroversion of the uterus. This rule is subject to one exception only: In performing the operation of shortening the round ligaments one of the ligaments may tear close to or out of the uterus. Under these conditions the abdomen should immediately be opened in the median line and the uterus sewn to the abdominal wall, ventral fixation being the lesser of the two evils when compared with leaving the uterus held forward by but one round ligament. I have three times performed ventral fixation under this indication. The same indication for ventral fixation holds good if the shortened round ligaments should slough after operation, and the uterus as a result again falls backward.

The above rules are based upon the assumption that shortening of the round ligaments is in every respect the most physiological operation for cases of uncomplicated retroversion, with no adhesions of uterus, tubes, and ovaries. I am quite free to admit that an anatomical cure of retroversion can be obtained by each of the three operations—vaginal fixation, ventral fixation, and shortening of the round ligaments—in from 90 to 100 per cent. of cases, by a proper technique and

[1] Case alluded to above and reported in Trans. New York Obst. Soc., Nov. 21, 1893, and April 17, 1894.

a capable operator. Mackenrodt figures 10 per cent. of failures for vaginal fixation. Kellogg, who has probably had the largest individual experience in shortening the round ligaments, writes me: "I have done the operation a few more than five hundred times, and have had failures or partial failures in less than 5 per cent. of the cases." My own experience, embracing over one hundred cases, tallies with this. In ventral fixation there is no reason why the average operator should not obtain from 95 per cent. upward of anatomical cures. The quality of the cure, however, is an entirely different matter, especially to the patient. After a successful shortening of the round ligaments the physiological mobility of the uterus remains unimpaired. In pregnancy the shortened round ligaments undergo evolution and involution with the uterus. The more successful, however, a ventral or a vaginal fixation, the greater the abnormalities established within the patient's abdomen or pelvis. It is repugnant to every surgical instinct to create unnecessary adhesions within the peritoneal cavity.

An indication for ventral fixation that may be allowed by some, is inability of the operator to perform the operation of shortening the round ligaments. Others again will not admit this, and contend that in that case the surgeon should either learn how to do the operation or send his patient to some one who can. Personally, in view of the evidence now in in favor of the operation, I consider it the duty of every one claiming to be a specialist in gynecology to make himself master of some method of shortening the round ligaments outside of the abdomen. Though Adams, one of the originators of the operation, said: "The operation is one that all and sundry cannot perform," I think that, with a knowledge of anatomy and a little practice upon the cadaver, any surgeon capable of doing a Bassini operation for the radical cure of hernia should be able to shorten the round ligaments successfully. Others have encountered the same difficulties and have mastered them in one way or another. Kellogg, after having performed 28 operations after Alexander's method, writes: "I am sure that had I not adopted a new method of performing the operation I should have felt it my duty to cease its performance." Kuester had abandoned the operation twice, when, stimulated by the examination of a successful case of Werth, he tried a third time and has become one of its most enthusiastic advocates. Mundé records his discouraging first experience, but with the courage of his convictions he persevered and mastered the operation. The writer himself gave up the operation after five more or less, generally less, successful cases, and only resumed it six months later, after he had elaborated in the dead-house the technique of his method of shortening the round ligaments.

Another, and to the writer's mind a very important, indication for ventral fixation of the uterus is as an adjuvant in the performance of combined operations for the cure of prolapsus uteri et vaginæ. It is in just these cases that I have derived the most unalloyed satisfaction from the operation, the necessary plastic work upon uterus, vagina, and perineum being supplemented by ventral fixation performed at the same sitting. I have performed ventral fixation upon this indication 16 times. Two of the patients became pregnant, and were safely delivered at term. Both remained cured of their former complete procidentia of the uterus and vagina when last seen, one four months and the other a year after confinement.

Another broad indication for ventral fixation of the uterus is as a closing procedure after operations upon the adnexa of such a character that the possibility of future pregnancy is excluded, as, for instance, when both ovaries and tubes are removed, the uterus being left. This indication will but rarely obtain with those who advocate and practice removal of the uterus whenever both tubes and ovaries must go. Those of us, however, who are not quite so radical, but who sometimes leave a uterus under these conditions, should make it a practice to attach the fundus to the abdominal wall in closing the incision of the latter. Without added risk we thereby insure permanent anteposition of the uterus.

Nearly in line with this indication is the performance of ventral fixation after operations in which tubes and ovaries, or at least one tube and ovary, are left, the uterus being unusually heavy. There is an unwillingness in some quarters to trust to shortening of the round ligaments to hold a heavy uterus forward. Personally, I am convinced that any uterus which is so heavy from chronic metritis that the shortened round ligaments cannot sustain it, had better be removed; and conversely, experience has taught me that uteri of even twice the normal weight are readily and permanently held forward by properly and *sufficiently* shortening the round ligaments.

We come now to a doubtful field, that of the operative treatment of adherent retroverted uteri, with appendages in good or fair condition. This

territory has until within the past few years been conceded to ventral fixation. In the course of time, however, various operators, the writer among the number, have learned how to deal successfully with this class of cases by applying to them shortening of the round ligaments. An incision is first made into the peritoneal cavity either through the posterior vaginal fornix or through the anterior abdominal wall, and all adhesions of the uterus, tubes, and ovaries are broken up. The incision through which this work has been done is then closed and the round ligaments shortened in the usual way. The writer has practiced this procedure a number of times by both the vaginal and the suprapubic route, but for reasons of technique, which this is not the proper occasion to enter upon, he prefers the suprapubic approach.

In this connection it might be mentioned that Kellogg, for reasons and with exceptions for which I must refer to his paper,[1] says: "From my present standpoint I would not think of performing the operation of ventral fixation without also shortening the ligaments, etc." I myself have never met, nor can I conceive, the case to which I would consider a combination of the two operations applicable.

Ventral fixation has been considered, even by some who ordinarily prefer Alexander's operation, as indicated in sharp retroflexion of the uterus. This indication, however, I cannot allow, since I have succeeded in curing the most aggravated cases of movable retroflexion by shortening the round ligaments.

There remains one indication for ventral fixation, which, as far as my knowledge goes, has as yet neither been mentioned nor acted upon. I refer to cases of uterus unicornis causing symptoms which, under certain conditions, cannot be relieved short of operation. The writer has at present under observation a young woman, married over a year, in whom coitus has never been consummated, owing to intense dyspareunia. On examination she presents a uterus unicornis lying transversely across the pelvis, the developed right half of the body lying upon the right linea innominata, and the cervix pointing to the left in the vagina. The diagnosis of uterus unicornis with rudimentary left horn was made by tracing the left tube to the junction of corpus and cervix The tender left ovary lies immediately on top of the tilted cervix. The slightest pressure upward upon the latter causes the same intolerable pain which is experienced upon the entrance of the male organ. Ventral fixation of the uterus, with perhaps removal of the left ovary, will probably cure. Shortening of the round ligaments is not applicable to uteri unicornis, the round ligament of the undeveloped side, with the tube, arising from the uterus at the level of the os internum.

In conclusion the writer begs to submit the following propositions:

1. Vaginal fixation of the uterus does not come within the sphere of legitimate operations in women liable to future pregnancy.

2. The indications for ventral fixation of the uterus should be limited to the utmost degree in women liable to subsequent pregnancy.

3. Ventral fixation is never indicated in uncomplicated retroversion of the uterus.

4. Inability of an operator to perform shortening of the round ligaments *may* be an indication for ventral fixation, but not in the case of one claiming to be a specialist in gynecology.

5. Ventral fixation is indicated, *as an adjuvant*, in the performance of combined operations for prolapsus uteri et vaginæ.

6. Ventral fixation is indicated as a closing step in all celiotomies in which the adnexa are removed and the uterus is left.

7. Ventral fixation *may* be indicated, *under exceptional conditions*, in cases of adherent retroversion, with tubes and ovaries in good condition.

8. Ventral fixation *may* be indicated in the most aggravated cases of uncomplicated sharp retroflexion. The writer has not met such a case not amenable to successful treatment by shortening the round ligaments.

9. Ventral fixation is indicated, under certain conditions, in cases of uterus unicornis.

The operation of ventral fixation of the uterus is also known as hysterorrhaphy, hysteropexy, ventro-fixatio uteri, ventri-fixatio uteri, ventri-fixura uteri, and suspensio uteri; altogether too many designations for one operation. Hysterorrhaphy means suture of the uterus itself, and not attachment of the uterus by suture to another tissue or organ. It is of parallel significance with trachelorrhaphy, and no more. Hysteropexy signifies attachment or fastening of the uterus, but does not specify to what it is attached. It may mean vaginal, vesical, ventral, or any other fixation of the uterus. Ventro-fixatio uteri is ungrammatical; *venter* is a noun of the third declension. A Latin word *fixatio* does not exist; therefore neither ventro-fixatio nor ventri-fixatio is allowable. Ventri-fixura is the only correct Latin designation; *fixura*, an obsolete noun (from *figere*, *fixum*), being preferable to *fixatio*, a coined noun.

[1] *Modern Medicine and Bacteriological Review*, 1894.

The name suspensio uteri has been recently applied by Kelly, who first proposed the term hysterorrhaphy to a slightly modified ventral fixation. Neither the modification of technique, however, nor the change of name commends itself to the writer. Suspensio uteri, hanging the uterus, might better apply to shortening of the round ligaments, after which operation the uterus is really *suspended* in normal anteversion. A Fellow recently related to the New York Obstetrical Society a case in which, misled by the term suspensio uteri, he had suspended the uterus free in the abdominal cavity by sutures passed through fundus and anterior abdominal wall, not, however, bringing the two together. Sutures an inch or more in length run free through the peritoneal cavity of that patient between fundus uteri and anterior abdominal wall. Truly, a little knowledge is a dangerous thing. The operator was quite surprised when informed that this was not Kelly's suspensio uteri, as a case of which he had reported it, but that he had unconsciously performed an original operation not likely to have either claimants for priority or imitators.

Ventri-fixura uteri should be the Latin, and ventral fixation of the uterus or ventral hysteropexy the English, designation of the operation in question.

INDICATIONS FOR VAGINAL FIXATION, WITH ESPECIAL REFERENCE TO THE BEHAVIOR OF PREGNANCY AND LABOR AFTER THE OPERATION.[1]

By HIRAM N. VINEBERG, M.D.,

ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL, MOUNT SINAI HOSPITAL DISPENSARY AND MONTEFIORE HOME FOR CHRONIC INVALIDS.

To fix the indications of an operation of such comparatively recent date, and one in which the modifications have followed each other in rather rapid succession, is not altogether an easy task. When I first began doing vaginal fixation, two and a half years ago, I did not purposely enter the peritoneal cavity, and, in consequence, was unable to directly break up any existing adhesions. Twenty cases were operated upon after this method. Of these there were five cases of mobile retroversions without any appreciable disease of the adnexa, and fifteen cases with more or less adhesions and moderate disease of some of the appendages. In the first group, the clinical and anatomical results were perfect in four. In the fifth they were good until six months afterward, when the woman tampered with herself to bring on a miscarriage at the third month. In the second group the results were good in eight cases, and in seven the backward displacement recurred in from three to twelve weeks after the operation. Among these seven failures there were four cases of congenital retroversion with adhesions. As a result of this experience I had for my own guidance limited the indications of vaginal fixation to mobile retroversions and retroflexions without any marked disease of the adnexa.

About sixteen months ago I changed the method of operating so that the peritoneal cavity was purposely opened, any existing adhesions directly broken up, the whole uterus delivered through the vaginal incision, as were also the adnexa, which were subjected to surgical treatment on conservative principles. Twenty-nine cases were operated upon after this manner. The anatomical cures may be said to have been 100 per cent., as the only case of partial relapse obtained in one instance in which the method was not carried out in its entirety. The period of observation of these cases varied from three to sixteen months. As the cases constituting this series comprised every form of adherent backward displacement, with more or less disease of the adnexa, the indications for the operation had virtually no limitation where a conservative operation was at all applicable. There was one form, however, of malposition, in which the operation, to my mind, was contra-indicated. I have reference to congenital retroversion. It is doubtful, in my opinion, whether we have any operative procedure that will invariably be attended with good results in this condition. Just at the time when the believers in vaginal fixation were commencing to feel that the indications for the operation were firmly established on a broad basis, even broader than that of ventro-fixation, as will be made clear later, came the disquieting reports of several cases in which serious trouble was encountered at labor.

Inasmuch as the influence upon gestation and labor has a very strong bearing upon the indications for operative procedures of this nature, I shall devote the remainder of time at my disposal to a consideration of that question in vaginal fixation, first giving a concise abstract of the cases hitherto published in which labor was more or less seriously complicated.

Case 1 (Strassmann).[1]—Intraperitoneal vaginal fixation; posterior colpo-perineorrhaphy; operator

[1] Read before the Section on Obstetrics and Gynecology, New York Academy of Medicine, Feb. 27, 1896.

[1] *Zeit. für Geb. und Gyn.*, *Band* XXXIII, pp. 510–514.

Dührssen; conception three months later; labor at full term; transverse position; difficult version; severe post-partum hemorrhage, arrested only by a compression abdominal bandage.

Case 2 (Strassmann).[1]—Operated on Oct. 4, 1893; operator Dührssen; vaginal celiotomy for myoma, size of an apple, attached to anterior uterine wall; defect in uterus closed by interrupted silk sutures, ends of which carried through the vaginal flaps; some vaginal fixation sutures employed in addition; as a result there was, so to speak, a melting together of the uterine vaginal walls; conception September, 1894; acute gonorrhœa of vagina and cervix during the following winter; came to the Poliklinik on May 24, 1895. There was then prolapsus of the cord; head was in the pelvis, lying in the vaginal fixated part of the uterus; cervix high up on the right side above the promontory; with one finger carried into the os the shoulder was felt; nothing done for 24 hours; then had an eclamptic seizure, afterward a chill; temperature 100°, pulse 104; tetanus of the uterus; unsuccessful attempt at version under narcosis, and finally Porro's operation. Death occurred an hour later—and autopsy showed chronic nephritis, free blood in the peritoneal cavity, and a hematoma in the right broad ligament.

Case 3 (M. Graefe).[2]—Operation May 6, 1894; vaginal fixation after Mackenrodt without opening the peritoneum; conception Nov. 30, 1894; colicky pains January, 1895. July 22, consulted in Graefe's absence Dr. Witthauer, who made out a transverse position, and observed edema of the feet. Again seen, Oct. 1st, uterus a hand's breath above the umbilicus, and very tense; transverse position of the child; cervix high up in the sacral cavity; attempts to change the position of the child ineffectual owing to the contractions of the uterus; shortly after had convulsions, amaurosis, urine contained a large precentage of albumin. Cesarian section, good recovery.

Case 4 (E. Wertheim).[3]—Operation by Schauta; method, Dührssen's. Five months after operation it is noted that the fundus is very closely and firmly adherent to the vaginal wall, "as if nailed to it." Labor at full term; cervix high up in the pelvis; transverse position of the child; under narcosis version after Braxton-Hicks method; delivery of a living child of eight pounds; good recovery. Some time afterward the fundus was still found lying against anterior vaginal wall, "as if nailed to it."

Case 5 (W. Rühl).[4]—Method vaginal celiotomy, with longitudinal incision; very extensive adhesions, leaving a raw surface on anterior uterine wall; vaginal fixation, result excellent; had been sterile 7 years; nine months later pregnancy; bladder disturbances; labor at term; seen 48 hours after labor pains set in; cervix high up in the right side; head in a diverticulum of the anterior uterine wall fixed in the pelvis; under narcosis head pushed up and cervix brought down; os dilated to admit four fingers; cartilaginous-like ring encircling os; with difficulty dilated os to admit whole hand; could not turn child; membranes had ruptured some time before; perforated head and incision of the cartilaginous ring; child easily delivered; afebrile recovery. Later uterus was found in good position.

Case 6 (W. Rühl).[1]—Vaginal fixation, with the fundus extensively sutured to the vaginal wall; pregnancy, bladder disturbances as in former case; labor at term; premature spontaneous rupture of the membranes; prolapse of cord; seen 24 hours after labor had set in; same local conditions as in former case; during examination, sudden cessation of the pulsations of the cord; incision in the anterior wall of cervix and body of uterus; child readily delivered with forceps; no hemorrhage worthy of mention; closure of uterine incision with catgut; afebrile recovery; uterus in good position several weeks later.

The same author reports three other cases of difficult labor at full term in which he did a version, saving the mother and the child.

CASES OF VAGINAL FIXATION IN WHICH PREGNANCY AND LABOR HAVE BEEN NORMAL.

W. Rühl[2]: Seven labors; method not stated.

E. Wertheim[3]: One labor; method probably Dührssen.

Strassmann (O. C.) reports 25 cases, several of which belong to Dührssen's series (estimate 10 cases).

Dührssen[4]: Seventeen cases; his own method.

Mackenrodt: Eight cases; his own method.

P. Wendeler[5]: Pregnancy at eight months; normal; method not stated.

Kossman[6]: One normal labor; vaginal celiotomy.

C. Staude[7]: One labor; Dührssen's method.

H. N. Vineberg[8]: Two labors and one pregnancy at seven months; method: modified Mackenrodt; vaginal celiotomy.

We thus have fifty-eight cases of labor, including two cases of normal advanced pregnancy, in which interference was necessary in nine cases as follows:[9] One Porro, one Cesarian section, two

[9] Even with faulty technique the showing is better than that following ventral fixation, where interference was necessary 11 times in 53 cases (Nieländer, *Zeit. f. Geb. und Gyn., Bd.* XXXIII, *Heft* 3).

cervical uterine incisions, and five versions. A further analysis shows that the difficulties obtained in cases operated upon after the Dührssen method, with a single exception—the case reported by Graefe. The report does not state the method of suturing nor the nature of suture material, both matters of vital importance in connection with the subject at issue.

When we investigate the nature of the difficulties we learn that they arose chiefly because the fundus was too firmly and extensively attached to the vaginal wall, necessitating the increase of the size of the uterus at the expense, principally, of the posterior uterine wall. This is just the contingency we might expect from Dührssen's method, in which a transverse incision is made in the anterior fornix at the vaginal junction, and the fundus attached by several sutures to the vaginal wall at this point.

Vaginal fixation, after the Dührssen method, therefore, has always been, in my opinion, faulty in technique, and has never been followed by me. My own experience, and that of others, have taught me that when certain points are observed in the technique of vaginal fixation no fears need be entertained of meeting with disturbances during gestation, nor with difficulties at labor. To be more precise: The superior fixation suture should be passed across the anterior wall of the uterus, one or two centimetres below the level of the insertion of the tubes, and through the vaginal walls one or two centimetres below the urethral meatus. Only two fixation sutures should be employed—the second a centimetre below the first. No scarification of the uterine wall should be made. The sutures should be tied on the vaginal wall, and removed at the end of three or four weeks. In my last two cases I carried out a technique which offers even less chance of any unfavorable influences upon gestation and parturition. After delivering the fundus, I passed a suture on either side, embracing the round ligament and a portion of the broad ligament adjacent to the uterus. These were carried through the vaginal flaps below the pubic arch at the side of the pelvis. In one of the cases, in addition, a suture was carried across the uterine wall in the usual manner, midway between the internal os and the fundus. The latter was employed to make more certain of the permanent result, though I think it may have been superfluous.

I have now arrived at a point at which, in a few sentences, I can formulate the indications for vaginal fixation as I understand and practice it.

It is indicated in all backward displacements of the uterus, with or without adhesions, and with or without diseases of the adnexa, in which surgical interference, for one reason or another, is demanded. It is particularly indicated when the backward displacement is complicated by moderate prolapsus of the uterus and prolapsus of the anterior vaginal wall. It finds an undisputed field in very fat subjects, with thick abdominal walls, in whom a ventral fixation constitutes a serious affair, and in whom an Alexander is extremely difficult of accomplishment. The same holds good in very thin subjects with thin and yielding abdominal parietes, so far, at least, as ventral fixation is concerned. The operation can be performed in nulliparæ, and even in virgins.[1] It is contra-indicated in certain cases of congenital retroversions. It should not be undertaken until a certain period has elapsed after the puerperal process, as the soft and friable condition of the uterus may lead to undesirable lacerations in the necessary manipulations to bring about anteversion of the organ.

NEGATIVE HISTOLOGICAL EXAMINATION OF THE BLOOD AS A FACTOR IN DIFFERENTIAL DIAGNOSIS.[2]

By WALTER A. WELLS, M.D.,
of Washington, D. C.

The very evident tendency of modern medicine to give greater prominence to those so-called clinical examination methods—physical, chemical, and microscopical—ought not, I think, to be construed as an effort to disregard, or even belittle, the value of close observation of the outward manifestations of disease, nor of the indispensable admission occasionally of anamnestic *data*.

We cannot fail to observe, however, that the latter functions are, with the progress of medicine, losing, in comparison with the former, their importance in the diagnostic art. To-day, instead of placing our chief reliance in history and symptoms, as did the earlier practitioners, we have relegated these to a somewhat subordinate position, and are inclined to pin our faith, rather, in the stethoscope, microscope, and chemical reagents.

These, it cannot be denied, are more precise, definite, and constant means, and are justified accordingly, from a scientific standpoint, in re-

[1] Among my cases there were four virgins and several nulliparæ, but they had been treated with pessaries and tampons for considerable lengths of time before being subjected to the operation.

[2] Read before the Clinical Society of the District of Columbia, January 13, 1896.

ceiving the high place which has been accorded them.

It is only very recently that methodical examinations of the blood have been made to serve the practical clinician; but there has been made in this short time such rapid and profitable advance, carrying with it such alluring promises of future possibilities, that there have appeared upon the field a succession of earnest and enthusiastic investigators, who have made and are continuously making valuable contributions in hematological studies. Would the medical practitioner but avail himself of those facts which stand confirmed by repeated observation, there would be certainly less excuse, if any at all, for ever confounding certain diseases which, without this aid, cannot be differentiated at times, even by the best diagnosticians; for example: pneumonia, in its commencement, from typhoid; typhoid from malaria; or even measles from scarlatina.

By the natural limitations of this paper, I am denied the consideration of the blood in various diseases, and even such instruments as the hemometer, hemaglobinometer, and hematocytometer. What information, then, is gathered by a mere examination of a specimen of blood under the lens? Beginning, as we should, with the fresh or native preparation, we may note the *rouleau* formation of the red blood-corpuscles, the fibrin formation in the plasma, the condition of the leucocytes, especially as to ameboid movement; the presence or absence of the plasmodium, better termed *hematobium malariæ*.

In the colored specimen we direct our attention first to the red blood-corpuscles. Are they altered in: (*a*) size constituting the so-called poikilocythemia? If so, do the microcytes (or smallest sized), megalocytes (large sized), or gigantocytes (excessively large sized) prevail? (*b*) Is poikilocytosis,[1] or, as Ehrlich prefers to designate it, schistocytosis, present? and if so, to what degree? (*c*) Are the erythrocytes abnormal as to the amount of coloring-matter contained in their discoplasma? We observe the size of the central dell. An alteration in the coloring-matter is designated polychromemia; and some writers term chlorotic those corpuscles which are poor in hemoglobin. (*d*) Are there present the nucleated erythrocytes, forms which do not occur at all in normal blood? If present, it is of importance to note whether the normoblasts only are present, or whether the mesoblasts, or yet more important the gigantoblasts, are to be seen. The leucocytes may next claim our attention. (1) An increase in their number can be detected through microscopical examination. There should be, according to Neudorfer, one leucocyte in about every fifth field. The presence of 1 to 2 leucocytes in the field constitutes a mild leucocytosis, 3 to 5 a moderate, and 5 to 10 a considerable. (2) We should, moreover, examine in reference to the relative distribution of the leucocytes, the preponderance of one or the other of the various forms constituting, respectively, a polynuclear leucocytosis, a lymphocytosis, or an eosinophilia. (3) Examination as to the number of the blood-plaques or hematoblasts; (4) as to the presence of the perinuclear basophiles; (5) as to the karyokinesis or karymytoses (the mitoses of Müller); and lastly (6) we may seek for micro-organisms, though this usually requires special staining, and is only exceptionally required. The blood must present then a normal condition in respect to all these in order that we may say that the histological examination yields a negative result. There are some diseases in which this is essentially the case which may therefore, I think, be fittingly discussed under this heading.

In the commencement, let me state it must not be supposed that a negative, that is to say a histologically normal, specimen can mean only a normal condition of the blood. On the contrary, there may be present a not inconsiderable anemia, which, because it does not extend to alterations in the character nor the relations of the elements, is not discoverable upon microscopical examination. Such may be the case in the so-called quantitative anemia, where, as it were, there is a general impoverishment of the circulating medium, an anemia in bulk, a parallel deprivation of all the elements without any disturbance of their relation to one another. In such an anemia we have therefore a color index represented by 1. We can illustrate this better, perhaps, by stating concrete cases. Let us suppose before us two individuals, both evidently suffering from a serious, exhausting illness, grave pathological condition of the internal organs, both being weak, emaciated, cachectic, and very pale, and there may or may not be signs pointing to a definite localization of trouble in lungs, liver, spleen, or other organ.

We take a specimen of blood from the one case, fix and stain orderly with, say, eosin-hematoxylon, and what do we find? In addition to an augmentation in the number of leucocytes, there are alterations of a high degree in the elements.

[1] Whether poikilocytosis is, as Maragliano's experiments seem to prove, but a form of necrobiasis artificially produced outside of the body, or not, does not alter its significance from a clinical point of view.

We have, in this case, to regard the poikilocytosis as a measure of the corpuscle's vitality.

There is poikilocytosis, poikilochromemia, megalo- and micro-cythemia, and we observe in the field also a number of nucleated erythrocytes. We now prepare a specimen in like manner from the other case and proceed to examine.

We see a different picture, and one that we may not have expected, in the case of an individual so manifestly anemic, with pale face and bloodless mucous membranes.

We can observe no signs of anemia in this blood upon microscopical examination, the leucocytes and erythrocytes are present in their normal relation to one another, and there are no departures from the normal as regards size, shape, or coloring. This patient is the subject of tuberculosis; the former has the blood characteristics of carcinoma.[1]

It is true that if we had used the Ehrlich tricolor stain we would in all probability have noted a deviation from the normal, because then it would be seen that the perinuclear basophiles of Neusser,[2] which are normally present, either failed or at least were lessened in number.

If we should proceed to the count of the corpuscles and to a measurement of the hemoglobin, the calculation of the color index[3] will result, as a rule, in 1 or thereabout, seldom less than .8.

It is surprising, as Grawitz[4] has shown, how little may be the reduction in the number of erythrocytes in tuberculosis, in spite of the apparent anemia. This he believed to be due to the peculiar effect of the absorption of tuberculous products, causing a condensation of the blood. His experiments upon animals demonstrated that injections into the veins of tubercular masses produced increased specific gravity of the blood, whereas the injection of extracts from cancer caused decrease of the red corpuscles and solid constituents of the blood.

The absence of the nucleated erythrocytes is one of the most important negative features of tuberculosis, especially as it is in this so distinctly opposed to cancer. It has been observed they are absent, or at least quite scarce, even after hemoptysis in tubercular subjects, although commonly a feature of anemia following hemorrhage. Tuberculosis is therefore, in its exemption from the erythroblasts, distinguished not only from cancer, but likewise from progressive pernicious anemia, leukemia and anemia infantum, pseudo-leukemia, and the anemias of tertiary syphilis and phosphorus-poisoning.

A second important negative feature of tuberculosis is the absence of leutocytosis.[1] Limbeck was, upon the strength of this single fact, enabled in three cases to make the diagnosis of tubercular meningitis, in contradistinction from the primary suppurative form, in which leucocytosis, usually of an intense degree, manifests itself, and found his diagnosis substantiated by autopsy. These observations, confirmed later by von Jaksch,[2] cannot easily be overestimated, on account of the evident bearing upon prognosis.

An interesting negative feature of the blood in tuberculosis is the absence of an increase of the fibrin-net—interesting because tubercular disease of the lungs runs sometimes the course of a pneumonia. The latter affection is marked as well by a high degree of polynuclear leucocytosis as by its great increase of fibrin. It seems that the Koch bacillus, unlike the diplococcus, retards the formation of the fibrin, and that it is less, therefore, in those cases of croupous pneumonia developing in tubercular individuals.

There almost never occurs eosinophilia in tuberculosis,[3] and this fact may also be made use of in differentiating it from certain affections in which an increase of these elements is the rule, namely, Graves' disease, myelogenic chlorosis, intestinal parasites, leukemia, nephritis, chronic malaria, and primary essential emphysema and asthma.[4]

We have pictured in the foregoing only the uncomplicated disease. It may be profitable to recall here briefly some of the modifications in this typical case which can occur by reason of complicating conditions. We may see a chlorosis of red blood-corpuscles where there have been: (*a*) hemorrhage, (*b*) excessive diarrhea, in (*c*) conditions giving rise to a great loss of albuminates, and (*d*) in case of complication with chlorosis.

A polynuclear leucocytosis in the course of tuberculosis pulmonum should awaken a suspicion of extensive cavity formation. A lymphocytosis

[1] It has been maintained by Bard that the blood may be independently the seat of cancer, and he has advanced the unique theory that leukemia is cancer of the blood.

[2] "*Ueber einer besonderer Blutbefund bei urathischer Diathese*," *Wiener klinische Wochenshrift*, 1894, VII, 727.

[3] The color index may be quickly estimated by dividing the number of red blood-corpuscles by 5,000,000, and then dividing the per cent. in hemoglobin by the result obtained.

[3] N. B. Botkin and Bischoff have seen considerable increase of eosinophiles after injections of tuberculin.

[4] Some authors have failed to find an increase of eosinophiles in the blood in asthma, but Gabretschewsky ("*Klinische Hematologischen Notizen*," *Archiv f. experim. Pathol. und Pharmakol.*, 1890-'91, 28) reports three cases in which the per cent. was 9, 10, and 22 respectively. At any rate the sputum of asthmatics ("*Gollasch zur Kenntniss des asthmatischen Sputum*," *Forthschritt d. Med.*, No. 10, 1889) will contain copious quantities of eosinophiles, which are always wanting or very scarce in tubercular sputum.

may exist as the expression of a quite general involvement of the glandular system. Very rarely one may have the type of a pernicious anemia. This could occur from the coexistence of sepsis, amylosis, nephritis, or carcinoma.

We pass next to the consideration of one of the essential fevers, the blood of which, though not in every respect normal under the microscope, yet at least presents negative features which mark it so clearly from others of its class as to entitle it to consideration under this head. I refer to typhoid fever, a disease in which all possible aids toward a diagnosis are to be welcomed, as the best clinicians confess themselves at times unable to make an early diagnosis. The most noteworthy negative feature of typhoid fever is the absence of a leucocytosis. Halla,[1] in 1883, made the general observation that febrile diseases were accompanied by the phenomena of leucocytosis. Limbeck,[2] at a later date, pointed out that leucocytosis occurred in only those inflammatory affections attended by exudation into the tissues, and mentioned typhoid as an affection exempt. This fact has been emphasized by Rieder,[3] Chetagraw, and Felsenthal,[4] and amply confirmed by clinical observation. Very often it is found, indeed, that the number of the leucocytes is under the normal; that, instead of a leucocytosis, there is a leukopenia. The decrease is at the expense of the polynuclear element, which may fall at the critical stage to 20 per cent., instead of their normal 64 per cent.; whereas the proportion of lymphocytes may rise to 50 per cent., instead of their normal 28 per cent. This relative lymphocytosis does not occur, however, until the second or third week. The diagnostic importance of a normal or, as the case may be, lessened number of leucocytes occurring in typhoid is seen when we know that but three other febrile affections present a similar condition of things, viz., measles, malaria, and tubercular meningitis.

We can easily exclude pneumonia, an affection marked by an intense leucocytosis. It also differs from pnemonia in showing no fibrin development. Malaria, even if search for the plasmodium should be negative, has positive signs in the usually found increase of pigment, hematoblasts, and eosinophiles. Endocarditis maligna, presenting at times a picture very difficult to distinguish from typhoid fever, may be excluded if leucocytosis be absent; so also any form of sepsis.

If, finally, from other symptoms, an irrefutable diagnosis of typhoid is justified, we must conclude a complication exists, as nephritis, pneumonia, otitis, parotitis. A polynuclear leucocytosis in the later stages—fourth or fifth week—may find its explanation in extensive ulcerations in the intestine that do not heal.

Measles, as already stated, presents a blood-type not unlike typhoid.

In the tendency toward a low number of leucocytes, especially of the eosinophiles, which Felsenthal found never over 1 per cent. (lowest normal limit), mark it very strongly against scarlatina, in which Katschetkoff[1] has found always leucocytosis, which at times reached 30,000, and in which eosinophiles varied from 8 per cent. to 15 per cent.

Other affections may be mentioned where the blood is essentially normal, as in primary syphilis, icterus neonatorum,[2] morbus maculosus Werlhofii, scorbutus (signs of regeneration in blood being usually wanting),[3] and benign growths; which facts may be of real use at times for diagnosis.

For instance, a dilatation of the gall-bladder or a hydronephrosis could in this be at least distinguished from echinococcus, because the latter is attended with eosinophilia.

In conclusion, I will mention an instance of negative examination of the blood leading directly to diagnosis, under circumstances somewhat unique. At a time when I was engaged in hematological studies at Neusser clinic, in Vienna—

A female patient, age 25, was admitted to the wards whose history was briefly as follows: As a child, had had rickets, measles, scarlet fever; menses began at 17 years, and have been since regular and normal.

At age of 13 suffered much from gastric troubles, for which she was under treatment in hospital seven months; vomited after eating, often a quantity of blood; had distate for sour food.

Present attack began three weeks prior to admission, and is similar to the former. Vomiting comes on ten to fifteen minutes after eating, and several times the patient declared there had been copious admixture of blood. There was tachycardia; respiration 58.

A provisional diagnosis of ulcus ventriculi was made in this case, and I undertook an examination of the blood, expecting to find the alterations

belonging to a post-hemorrhagic anemia; that is to say, in addition to slight leucocytosis, some nucleated red blood-corpuscles, a predominance upon the field of microcytes, and an increased number of the so-called hemoblasts, or blood-plates of Bizzozero;[1] but, to my astonishment, these changes were not to be seen, and the result of a thorough analysis was a normal condition of the blood.

The following day the case was demonstrated by Neusser in the lecture-room, and diagnosis was reached of hysteria, with hysterical vomiting, the vomiting of blood, which had not been seen by any one else, being discredited on the strength of a failure of post-hemorrhagic changes. Neusser laid chief stress upon the hematoblasts, which he holds to be important signs of regeneration in the blood, and whose presence in large numbers, therefore, he regards as favorable. He believes them to arise from the shed-off epithelium of the vessels; differing from Bizzozero, who thought they arose from the destruction of the white and red blood-corpuscles, and Löwitt, who supposed them to be the products of the destruction of the leucocytes or precipitates from the plasma, and therefore degenerative changes. According to Hayem, they are steps in the formation of erythrocytes. At any rate, their presence is not to be expected until a day or so after the loss of the blood.

The diagnosis in the case in question was corroborated by the discovery of the so-called hysterical stigmata. An interesting feature was the absence of hydrochloric acid from the stomach secretions.

If I have succeeded in demonstrating that blood analysis is more frequently demanded than was formerly supposed, and may be helpful to diagnosis at times, even though negative in its result, and have thereby added any incentive for greater attention to that department of investigation which certain observers believe offers a hopeful medium for the solution of many dark problems in physiology and pathology, then my object in presenting this paper has been accomplished.

Under the laws of the State of Louisiana the New Orleans *Medical and Surgical Journal*, Ltd., was incorporated last month. It is our sincere hope that this departure will insure a long and successful career for our esteemed Southern exchange.

CLINICAL MEMORANDA.

SOME OF THE USES OF STROPHANTHUS.

By W. K. WADLEIGH, M.D.,
of Hopkinton, N. H.

Strophanthus is by no means a new remedy—a memoir of its physiological action was presented to the French Academy of Sciences in 1865, thirty years ago. Dr. Fraser began to study it in 1869, but it was not until 1885 that he gave it a definite place in therapeutics as a heart tonic. The physiological action of strophanthus, generally speaking, may be said to be similar to that of digitalis, but there are some points of difference. Unlike digitalis, it has very little, if any, power to contract the small blood-vessels, in the ordinary medicinal dose. As a diuretic, it is much more sure and certain than digitalis, acting probably on the Malphigian tufts. The effect produced by strophanthus is almost immediate, though not so prolonged as that of digitalis, and it almost never produces any unpleasant stomach symptoms, no matter how long administered.

This is a point of practical value, as it not unfrequently happens that the administration of digitalis has to be suspended, or even stopped entirely, on account of the derangement of the stomach, which is sometimes produced even by the smallest doses. In large doses strophanthus acts not only on the heart muscle itself, but upon the entire muscular structures of the body. In poisonous doses it will cause nausea and vomiting, and acts as a depressant to the respiratory centres, and finally causes death, usually by asphyxia.

Clinically, strophanthus may be used with more or less benefit in all cases where digitalis is indicated, not that it will do as well in all cases, but if digitalis has failed, or has had to be discontinued for any reason, we have in strophanthus a valuable substitute; but it is more especially in a few conditions in which digitalis is not so generally applicable that strophanthus finds its chief usefulness:

1. Among aged people, generally speaking, I have found strophanthus to give much better results in almost every condition where this class of remedies is indicated. In old age we often find an atheromatous condition of the arteries; and although digitalis may not be positively contra-indicated, in all such cases it is very apt to do little good, and sometimes may even do harm.

2. In vertigo of aged people caused by cerebral anemia or by a lack of balance between the different parts of the circulation of the brain. This is something we find very little about in the books, and it is a condition in which I have been able to do much good with strophanthus.

3. In angina pectoris. My experience with strophanthus in this disease has led me to believe that it will benefit a larger number of cases than any single remedy we possess.

4. In general anemia and chlorosis when accompanied by weakness of the heart, as so often happens in these diseases, it not only gives great relief so far as the heart symptoms are concerned, but, by sending more blood to

the tissues, increases their nutrition in this way. It is often an advantage to combine it with nitroglycerin in anemia.

5. In the so-called irritable heart characterized by palpitation on slight exertion, more or less pain in the region of the heart, often quite severe, weak, quick pulse, sometimes intermitting, but with no organic disease of the heart present. In this condition we may give strophanthus with almost an absolute certainty of deriving benefit from its use. This class of cases is quite numerous, and I have yet to see the case which strophanthus will not benefit, and it will often cure them.

I have been using strophanthus now for about seven years, and during that time have given it in a good many cases, and in fact I consider it one of the most useful remedies we have. It is impossible to give a report of many cases, because I have not kept a record of them. I will, however, mention two or three cases which may be of interest:

Case I. Mrs. C., 56 years old; history of organic heart disease for several years. On being called to her I found the following conditions present: Very marked mitral regurgitation, considerable dilatation, anasarca of the lower extremities to the knees, great dyspnea so that the patient was not able to lie down at all, more or less edema of the lungs, with incessant coughing. Prescribed digitalis, ten drops every two hours, .1 grain of calomel every hour, with stimulants. Two days of this treatment produced very little or no results whatever. Convallaria was next tried, with no better result. Nitroglycerin gave some temporary relief, but nothing permanent was really accomplished until strophanthus was used, the good effect of which was apparent almost immediately. In twenty-four hours she was able to resume the horizontal position, and the improvement was continuous from this time on, the anasarca mostly disappeared, excepting some slight swelling about the feet and ankles, and she was able to get about the house and attend to her household duties. At this time the remedy was discontinued and she soon returned to the same condition in which I first found her.

Strophanthus was again administered, with equally good result. She went through this same process three times and she then passed from under my care, and her next attack proved fatal. This was the first case in which I used strophanthus. The largest dose administered was twelve drops, and I have never found it necessary to exceed this amount in my subsequent cases. I do not know why digitalis did not succeed, or why so much greater benefit should be derived from strophanthus, as the conditions present would seem to point to digitalis as the remedy.

Case II. Mr. K., aged 86. History of temporary insanity some thirty years before. Found him in a generally enfeebled condition, and troubled with vertigo so that he was unable to walk without assistance; when he attempted to do so he would almost invariably fall. Began to give strophanthus and in two weeks he was able to walk without assistance.

This was supplemented by other treatment as occasion required. I made several attempts to discontinue the strophanthus, but each time I did so I found him returning to his former condition. He took the remedy almost continuously for five years, until the time of his death. This case is of interest for two reasons: First, it illustrates the benefit which may be derived from the use of strophanthus in cerebral vertigo of old people, of which I have already spoken, and it also shows that it may be given for a long period without any unpleasant symptoms arising from its use. So far as I know, this is the only case which has been reported where strophanthus has been given continuously for so long a time.

Case III. Angina pectoris. Male, 46 years of age. Had been suffering from the disease about two years when he first came under my care. Treatment five drops of tincture of strophanthus with two drops Fowler's Solution three times a day. His attacks soon became less frequent and severe, and improvement continued as long as he used the remedy. He had been obliged to take one-half grain of morphine two or three times a week for the relief of the paroxysms, but was soon able to discontinue this. In this case nitroglycerin seemed to augment rather than relieve the severity of the paroxysms. He died of this disease last winter, some time after he had passed from under my observation. This is only one of several cases of angina where I have given strophanthus, and it has always given more or less relief with the exception of one case. This patient could not take it, for some reason, and it had to be given up.

The best preparation of strophanthus is the tincture prepared from the seeds. The dose given is one to ten minims; it is rarely necessary to give it in larger doses than five drops, three or four times a day.

TOXIC SYMPTOMS PRODUCED BY PIPERAZINE.

By CHARLES H. P. SLAUGHTER, M.D.,
of Philadelphia.

The compound whose toxic symptoms are about to be described is a comparatively recent one, being introduced by Merck as an antipodagric and antirheumatic. Very little is known, as far as the writer can ascertain, in regard to its physiological, toxic, or therapeutic action. Chemically, it is a diethyl-diamine ($C_4H_{10}N_2$).

The following case has come under my observation: Maud E., married, of English birth, 32 years of age and a sufferer from uric-acid diathesis, applied to me for treatment on December 10, 1895. I placed her on the ordinary remedies for such complaints, but with negative results. On December 16, 1895, I was summoned to her home, and found her complaining of quite marked vesical irritability and tenesmus, being now confined to her bed. Upon examining the urine I found it rich with uric acid. To overcome the marked acidity of the renal secretion, and, at the same time, cherishing hope that the diathesis would be favorably influenced, I ordered her the following prescription, viz.:

℞

Piperazine 3i

Fiat chart. No. iii.

directing one of these powders to be dissolved in a pint

of water, the whole to be consumed during the following 24 hours. This was about noon.

Mr. E., the husband, took the prescription to the drug-store and had it compounded. Forgetting just how the potion was to be administered he inquired of the drug clerk, who directed him, with the customary wisdom, to dissolve a powder *in a teaspoonful of water* and give at once. When the husband arrived home he relieved himself of the directions which the druggist had given, but the wife remembered my statement that a pint of water was to be used to dissolve the powder. This she did, and drank the entire pint, containing 20 grains of piperazine. When the proprietor of the store returned the clerk informed him how he had directed the man to give the medicine. Realizing that this was a rather potent dose, the proprietor hastened to the patient's house, only to find that the entire 20 grains had been taken. He called on me at about 5 o'clock, relating the above circumstances and stated that the patient's pulse was good.

I saw the woman at 7:30 P.M. She was greatly cyanosed and semi-comatose, it being necessary to arouse her to obtain any reply to inquiries. Her pupils were minutely contracted, the pulse 50 beats per minute and slow, temperature 97.4° F. The respirations were very much depressed and a low muttering delirium prevailed. The tips of the fingers and lips were cyanotic, and on attempting to walk complete loss of motion was observed in both lower limbs, while sensation was well preserved. The symptoms were indeed most alarming.

Appreciating the gravity of the situation which confronted me, I administered cardiac and respiratory stimulants, using at the same time external heat and elevating the lower limbs. The woman also received a high stimulating rectal injection and was catheterized. It was only after several hours of the above treatment, persistently administered, that reaction occurred.

The next day I visited her and found the loss of motion returning and also a marked hypostatic congestion of both lungs. Upon the sixth day the paraplegia had vanished and the woman finally made a complete recovery. The paralysis was treated with large doses of strychnine and massage.

MEDICAL PROGRESS.

Experimental Addison's Disease.—At a recent meeting of the Société de Biologie, Boinet (*Semaine médicale*, 1896, No. 8, p. 62) related the results of a series of experiments directed to the artificial production in animals of Addison's disease. It was found that lesions of the suprarenal capsules were followed by an accumulation of black pigment in the blood and an infiltration therewith of a large number of organs and tissues. From 109 rats both suprarenal glands were removed; the glands of 20 were ligated, and in a third series the glands were cauterized by means of tincture of iodine, silver nitrate, ferric chloride or zinc chloride, or irritated with pus from inflammatory or tuberculous lesions. The black pigment, which was like that found beneath the skin and the mucous membrane and in several organs from two fatal cases of Addison's disease, was found in the blood in notable quantity in half of the cases, in smaller quantity in a quarter, and not at all in the remainder. In a number of animals whose suprarenal capsules had been irritated or removed several months previously, there was also an infiltration of the pigment in the subcutaneous cellular tissues, in the lumbar and mesenteric glands, in the peritoneum, in the mesentery, under the fibrous capsule, and in a cyst of the kidney, in a cyst of the liver, in the superficial portions of the spleen, in the lung, in the prevertebral cellular tissue, at the surface of the brain, in the bony marrow, and in the muscles. Sometimes marked muscular paresis, with gradual asthenia, completed the analogy with Addison's disease. Finally, injection of an extract prepared from the muscles of such rats induced fatally toxic results in other rats, especially if the suprarenal glands were previously irritated or removed.

Hernia of the Vermiform Appendix.—Sendler (*Münchener medicinische Wochenschrift*, 1896, No. 5, p. 96) has reported the case of a male infant, 5 weeks old, presenting a telangiectasis of the right thigh, a small umbilical hernia, and a slight hypospadias, who, after mild signs of illness for a day or more, was seized with vomiting of greenish matter, while the bowels were constipated and even flatus was not expelled. The condition soon became alarming, pallor and other signs of collapse manifesting themselves, and relief not following hot baths and high rectal injections. It was now observed that a slight swelling had formed in the right groin and right side of the scrotum. The umbilical hernia was readily restored, but the swelling in the right groin was tense and elastic and could not be dissipated. Incarcerated inguinal hernia was diagnosticated, and after a prolonged hot bath and attempted reposition under ether, without success, an incision was made over the swelling in the groin and the hernial sac exposed. In the sac was found the vermiform appendix, which was about two inches long, reddish-brown in color, and swollen and flexed in the middle, and situated like a bar before the inguinal opening. The appendix, which was provided with a well-defined mesentery, presented a furrow resulting from the strangulation, but the cecum appeared healthy. The appendix was ligated at its base and removed, and the stump covered with serous membrane and inverted into the cecum. The inguinal ring was divided, the cecum returned to the abdomen, the hernial sac largely extirpated, and the canal finally closed by suture. The further progress of the case was free from complication, and the child was dismissed at the end of a week with a gain in weight and all its functions well performed.

Tabes Dorsalis as a Disease of the Neuron.—Moxter (*Zeitschrift für klinische Medicin*, B. XXIX, H. 3, 4, p. 334) reports an interesting case of tabes dorsalis under observation at the clinic of Prof. Leyden, Berlin, in support of the hypothesis that the disease is primarily an affection of the neuron. The patient was a woman, 57 years old, in whom double optic atrophy developed in the course of four months, leading to almost total blindness. In addition there were lancinating pains in the lower ex-

tremities, girdle-sense, and radiating pains paroxysmally in the face and head. Death resulted in consequence of disease of the heart. Post-mortem examination disclosed evidences probably of tertiary syphilis (atrophy of the glands at the base of the tongue, in conjunction with arterio-sclerosis). Upon microscopic examination, numerous atrophic fibres were found in the peripheral nerves. The arachnoid throughout the cord presented evidences of chronic inflammation. The lowest roots of the posterior nerves in the cauda equina were the seat of only slight changes. In the posterior columns of the sacral and lumbar portions of the cord were ill-defined areas containing a relative deficiency of fibres. The posterior roots from the 5th dorsal to the 8th cervical contained atrophic fibres arranged in bundles and whose medullary sheaths failed to take appropriate stains. In the same region the intramedullary fibres were greatly rarefied. In the posterior columns from the 5th dorsal segment upward were two well-defined areas, showing an increase in glia and an absence of fibres, but no loss of fibres could be demonstrated above the nuclei of the posterior columns. The gray matter of the lumbar and sacral cord contained an area of destruction and disappearance of ganglion-cells, with increase in the glia and disappearance of the medullated nerve-fibres. Above this, destructive changes had taken place in the anterior horns of the gray matter. In the retina the cells of the ganglion-cell layer were greatly rarefied, and the nerve-fibre layer was altogether wanting. Some fibres remained in the papilla and in the optic nerve. A similar loss of fibres was present in the chiasm, while the cells of the pulvinar and of the geniculate body were unaffected.

Lead Gout and the Influence of Lead Intoxication upon Uric-acid Excretion.—As the result of a careful clinical study and a survey of the literature of the subject, Luethje (*Zeitschrift für klinische Medicin*, B. XXIX, H. 3, 4, p. 266) maintains that there can be no doubt that an intimate relation exists between lead intoxication and gout. It is probable that by itself, without the aid of other etiologic influences, lead is capable of causing gout. Intoxication with lead has no influence upon the excretion of uric acid; so that the gout-inducing activity of lead is not due to retention and accumulation of uric acid. The presence of uric acid in the blood of those suffering with lead intoxication is to be attributed to an excessive production of this acid. How this is brought about cannot at present be explained. In all probability lead is capable of inducing "gouty necrosis." In order to cause gout the intoxication with lead must have been of long standing. The clinical course of lead gout differs in several particulars from that of the ordinary form of gout: (*a*) The first attack usually occurs at a relatively early period in life. (*b*) There is a tendency for many joints to be involved in rapid succession. (*c*) Often joints are involved that usually escape in the ordinary form. (*d*) The tendency to the formation of tophi and of deformities is more than ordinarily pronounced. The prognosis is always dubious. Examination of the urine of a dog poisoned with lead showed that xanthin bodies comprised about half of the nitrogen of the alloxur bodies. After feeding with thymus gland, xanthin bases could be found in the blood, but no uric acid.

THERAPEUTIC NOTES.

The Treatment of Urinary Lithiasis.—In the attack of renal colic the patient should be placed in a warm bath and there kept for an hour. Of the following solution 15 minims should be injected hypodermically at once, and thereafter 8 minims every hour until the pain subsides:

Take of:

Morphine hydrochlorate	$2\frac{2}{3}$ grain
Boiling water . .	$1\frac{1}{2}$ fluid drams.—Mix.

Besides, a pill containing 1-6 gr. each of powdered opium and powdered belladonna should be taken twice daily. In the intervals between the paroxysms the patient should abstain from dark and smoked meats, from game, sorrel, asparagus, peas, tomatoes, and spinach. He should avoid also all alcoholic and aerated beverages, as well as tea and coffee. He may eat white meats, well cooked, eggs, light fish, farina, and fruits, fresh or stewed. He may drink white wine half diluted. He should take daily exercise in the open air, but should avoid excesses of all kinds. Every morning the surface of the body should be rubbed with flannel gloves. A simple bath may be taken every third day. Before each meal 15 grains of lithium benzoate may be administered well diluted. Any pure water or litha-water may be taken freely. — *Tribune médicale; Progrès médicale*, 1896, No. 2.

Urea as a Diuretic.—Governed by a knowledge of the solvent action of urea upon uric acid, Klemperer (*Berlin. klinishe Wochenschrift*, 1896, No. 1, p. 6) was led to employ the first-named agent, medicinally, in the treatment of a number of cases of uric-acid renal calculi. The results were entirely satisfactory. It was noticed besides that conspicuous diuresis resulted also. For this reason it was concluded to employ urea as a diuretic, and in two cases of cirrhosis of the liver attended with ascites it was thus used and caused the disappearance of the peritoneal effusion. The agent was given dissolved in distilled water in the proportions of from 1 to 20:200 (from gr. xv to ℥ v to about f ℥ vij) to be taken daily in tablespoonful doses at intervals of an hour. The taste of the drug is not agreeable, but is readily removed by drinking milk after the ingestion. No ulterior influence was exerted upon the appetite or digestion of those using the agent. For its action as a diuretic, a healthy state of the renal parenchyma is necessary.

For Uterine Leucorrhea.—

℞	Acidi Tannic. . .		℥ ij
	Alcohol. pur.		
	Creosoti . .	aa	f ℥ ss.
	Aquæ destil. . .		f ℥ viij.—M.

S. Add a tablespoonful to a quart of warm water, and use three or four times a day as a vaginal injection.

—Lirola, *Progrès médical*, No. 6.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to The Medical News will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

Address the Editor: J. RIDDLE GOFFE, M.D.,
No. 111 Fifth Avenue (corner of 18th St.), New York.

Subscription Price, including postage in U. S. and Canada.

Per Annum in Advance	$4.00
Single Copies	.10
With The American Journal of the Medical Sciences, Per Annum	7.50

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, MARCH 14, 1896.

IS NEW YORK TO HAVE ITS MOLOKAI?

If it be true that misery likes company there must have been rejoicing when the doors of the North Brothers Leprosery were thrown open to admit the latest victim of this uninviting disease. The lot of the four patients who have been confined in this temporary lazaretto during the past few months must have been happiness itself compared with the fate of Ding, the Chinaman who died a year or so ago, forsaken and forlorn, the sole inmate of a rude hut erected on the extremity of the island. Here, without the consolation of a word spoken in a tongue he could understand, longing and hoping day by day that he might be sent back to the Flowery Kingdom, and suffering more from nostalgia than from his actual disease, he finally refused to partake of the food passed in at the door of his living tomb, and perished miserably.

Well might the writer of his obituary in a German paper at the time, call him "*Armes Ding*," for he had been poor indeed. Another Chinaman is there now—Long Dong. Their very names ring out their knell! He, however, has companions: Bryan and Peters, who are negroes; Dalco, an Italian; and now a native of the United States, who has lived in this city for seventeen years, has joined the outcast band.

This man is a cook, and it would seem either that this occupation predisposes to leprosy, or that lepers are especially apt to seek a livelihood by catering to the wants of the inner man. It will be recalled that the leper who created so much discussion, and a certain amount of lepraphobia in Philadelphia several years ago, was a hotel cook in that city. A few years previous to this an American woman who had resided among lepers in South America, was discovered with marked manifestations of the disease, while acting as cook in a Philadelphia restaurant. Several of those who have from time to time been inmates of the New York City Hospital have given the culinary art as their occupation. Within a few months a domestic in a private family in Boston was found to be leprous, but whether or not she did the cooking has escaped us. Evans, who died during the past year in the City Hospital, and who was for a long time under the writer's care, came to this country from Bermuda at the age of 12 years, and was here for two years before signs of the disease showed themselves. He then returned to Bermuda, and subsequently took a trip on a vessel as cook, or cook's helper.

"Vic," who was also at one time a patient of the writer's, was a noted cook, and a particular stew which he manufactured at the Colored Home was held in high esteem by the hospital inmates, when they were fortunate enough to be in his good graces. "Vic" and his stew are, however, things of the long since past, and we must return to things present and to come.

Does the American leper have a fair show?

In a New York newspaper of recent date appeared the following dispatch from Minneapolis;

"A case of Asiatic leprosy has been discovered in the western part of Grand Forks County, North Dakota. The victim is Jens Olsen, a Swedish boy, 17 years old and an orphan. The county commissioners have had a small cabin built for him on a farm, and he will be kept there alone."

Is this really the threshold of the twentieth century on which we stand? Are we living in a Christian land? Can we call ourselves civilized?

Is it not enough to be an orphan and a leper without being condemned to an eternity "alone"?

Even if the report of such an outrage is not true, it has gone out to the world as the American modern method of caring for these unfortunate creatures, and we have seen the same methods applied at our very doors. At the third meeting of the Congress of American Physicians and Surgeons in Washington, the question of national control of leprosy was fully discussed, and the following motion was adopted and directed to be transmitted to the proper Committees of the Senate and House of Representatives:

"Whereas, The American Dermatological Association recognizes the importance of the undoubted existence of leprosy in North America; therefore

"*Resolved*, That the Congress of American Physicians and Surgeons be requested to memorialize the Congress of the United States of America, with a view to the appointment of a commission of five to investigate the prevalence of leprosy in the United States of America, and in countries upon its border; and to suggest means for the control of the disease."

No action seems to have been taken upon this very reasonable request. In the mean time the leper population has begun to cause trouble under inadequate city and State control.

In Louisiana, where the necessity for action has become imperative, a hospital has been established on the Mississippi, made up of eight cottages surrounding a fine old plantation house; but in spite of the "Arcadian scenery" and other attractions of the place which offers accommodations for one hundred inmates, few can be induced, without the use of force, to avail themselves of it. From recent reports the disease would appear to be increasing at the expense of the native-born population in and about New Orleans, and it would seem to be as much a matter of national as of State interest to check its spread.

As far back as 1888 Dr. Blanc reported 42 cases of leprosy, 29 of which were in natives of Louisiana, and 22 of the city of New Orleans.

As to the existence of leprosy in countries upon our borders it is to be found in Canada, British Columbia, Mexico, Cuba, and the West Indies in general. In Havana a leper-house was established as early as 1681, but the disease had begun to diminish until a decided Chinese immigration set in. Now it is difficult to say how many lepers are on the island, but the hospital itself usually shows a census of little less than one hundred.

In Jamaica the leper population has been estimated at 450, or 1 to each 1380 of the residents of the island. To be sure, our little band makes a poor showing alongside of these figures; but if a suitably attractive resort were established, we could in time keep it respectably filled. Brooklyn would send from three to five good cases at once, Harlem could contribute, and the eligible stray subjects about town might be glad to avail themselves of the hygiene and science to be found in an up-to-date New York Molokai.

DEGENERACY AMONG THE DOCTORS.

The recently enunciated theory of degeneracy is applicable to doctors of medicine, and the condition is mild or pronounced according to one's mental point of observation. One of its characteristics, which is most frequently manifested, is vanity: not the bombast and quackery of charlatans and mountebanks; not the stiffness and excessive decorum veneering over an insignificant stock of knowledge which were so transparently evident to Molière, who covered with ridicule the physicians of his day, and made these types conspicuous for all time. No, the average doctor of the present day knows more and has more common-sense than was the case with either of the types in question; besides there are few communities so deficient in perception that they would long tolerate either of them.

The doctor of to-day shows his vanity by attaching to his name on every possible occasion all the titles and distinctions that have ever been conferred upon him. He announces with his signature that he is the present incumbent of several offices, and the late or *sometime* incumbent of several more.

Ethical scruples do not prevent the doctor, who is thus degenerate, from heralding in the medical journals (and sometimes in the daily press, but this is *entre nous*) the account of some wonderful operation or some revolutionizing method of treatment, *provided* the patient gets well; otherwise the discovery dies with the patient.

Another evidence of degeneracy among doctors consists in the wild delusions that prevail concerning the exercise of charity. We do not

mean to imply that there are not many doctors who are truly charitable, benevolent, beneficent. There are many who are thus charitable to a marked degree. But there is a difference between that charity which does not let "the left hand know what the right hand doeth" and that which is announced with trumpets. How many doctors, even though they may occasionally pay for the board and nursing of interesting subjects out of their own funds, would do so if the personal, individual, selfish element, the hope of glory or gain, either directly or indirectly, were entirely eliminated? Strip off the mask, call it love of science, or, more honestly, the desire for personal advancement, which is proper enough in its place, but do not misname it charity and seek contributions from the public treasury under that misnomer. The earlier the public learns to differentiate between the true and the spurious medical charity the better for all concerned; the public will become more discriminating and the doctors more honest.

The acme of degeneracy is reached by those doctors who seek to impress the community, lay as well as professional, by the publication of statistics of methods or operations or cures. If fatal cases are mentioned at all they are usually explained away by any means other than lack of judgment, of skill, of foresight, or of proper care. Such publications confirm the appropriateness of the late Lord Beaconfield's remark that lies were of three varieties,—"lies, d—d lies, and statistics."

They invade the realm of fiction and poetry, borrowing from the *imagination illimitable*, or as an alternative, they are the product of a bad memory. One whom we have always regarded as honest recently boasted of the performance of X major operations without a fatal result. We were tempted to exclaim, *et tu Brute?* Another eminent and respected friend stated that his records had been lost, but that he thought he had opened the abdomen at least a thousand times,—an incredible number to those who are familiar with his practice. A young surgeon of this city is said to have stated to one upon whom he operated for appendicitis that he had seen two thousand cases of this disease.

Some doctors are so accustomed to exaggeration when speaking of their work that they seem to believe their own statements, and apparently seek to convince their hearers of their truthfulness. They evidently misinterpret the smile of incredulity when they reduce their statements to figures.

Statistical statements not only admit of exaggeration, but of a mysterious process of exclusion when it becomes necessary to refer to cases which have resulted fatally. Everybody knows that certain cases are doomed, whether they are operated upon or not; that with others there is a bare chance of success if an operation is performed. Suppose the operation is performed and the patient dies. The inducement may have been a large fee, or the desire and hope of relieving distress and saving life, or both. Everybody knows that either motive may sway one, and sometimes either may pervert the judgment. But the history of such cases, which is profitable alike for instruction or warning, seldom becomes known.

A further evidence of degeneracy is seen in the misleading and untruthful character of certain statements which are published in the daily papers, and which are inspired, of course, by medical authority. We do not forget that due allowance must be made for inaccuracies on the part of reporters. For example, in the New York *Times* for February 20, 1896, was an article which stated that the operation of appendicitis had a mortality of 2 per cent. We doubt whether such success is possible to even the most brilliant and most skilful surgeons, for they are the very ones who are called upon to see and treat the most desperate cases. It would be interesting to know how those cases are classified, not inconsiderable in number, in which the diagnosis is erroneous, no disease of the appendix being found when the abdomen has been opened. These evils, blights upon character, faults of morals as well as of intellect, which have been referred to, certainly without unkind feelings toward those who have manifested them, are often the product—one of the by-products, shall we say?—of success. The unsuccessful man is seldom a boaster, and has no statistics to inflict upon his hearers whenever he rises to debate a question. Medical degeneracy is therefore allied to success, at least in many instances; but it is admitted that the condition

does not vary greatly from that which often attends success in other walks of life where riches beget arrogance, luxury, and even untruthfulness. Its cure is not diminished professional assiduity, not diminished striving for ideal limits to the grand work which Medicine proposes to her votaries, but greater self-control, greater modesty of statement, and greater zeal for the absolutely and accurately truthful.

DERMATOLOGY.

A CRITICAL RESUME OF RECENT PROGRESS.

What part diet plays in the etiology and treatment of diseases of the skin is still undetermined. The difficulties involved in a proper study of the subject are very great, as idiosyncrasy enacts so large a part in the effect of any diet. "One man's meat is another man's poison" is a familiar and true saying. While there are a few diseases of the skin that are due to diet without a doubt, such as pellagra and urticaria, in most dermatoses no such connection is proved. In the last meeting of the British Medical Society diet as a factor in skin diseases was discussed in the Section on Dermatology. Dr. W. G. Smith, in his paper (*British Jour. Derm.*, 1895, VII, 309), took what seems to me the true view in regard to diet; and that is, that, although there are only a few foods which have an undoubted tendency to cause skin diseases, still an improper or insufficient diet is an etiological factor in many dermatoses, as it induces a condition of malnutrition that renders the patient susceptible to all sorts of accidents, skin diseases being among them. It is therefore eminently proper to improve the nutrition of a patient with a skin disease, by improving and regulating his diet, as well as by other means. The conclusion of Dr. Smith's paper is very commendable. He says: "Moderation and temperance in all things are the only rules for diet. The avoidance of alcohol, the regulation of the bowels, and the cure of anemia are more important than any special diet."

Bacteriological science is constantly shedding new light upon the etiology of skin diseases. One of the latest diseases shown to be parasitic is trichorrhexis nodosa. We knew very little as to the cause of this peculiar malady. It was thought by some to be due to handling the beard, by others to be a neurosis. In 1894 Hodara found a bacillus in constant relation to the disease as it occurred in the scalp hair of women in Constantinople. Now Essen (*Archiv f. Derm. u. Syph.*, 1895, XXXIII, 415) has succeeded in making pure cultures of a bacillus from a case affecting the beard, and in reproducing the disease from the cultures. The bacillus of Essen was never found on sound hairs, and it was not the same as the one found by Hodara. Unfortunately for the absolute success of Essen's investigations, he was unable to find the bacillus on the diseased hairs of the subject of the inoculation experiment. It is evident that the disease is parasitic and that the subject merits further study.

Up to a year ago it was not known that mycetoma, or the fungus-foot of India, existed in this country. It then so happened that two cases were reported in one year, one by Dr. Adami, of Montreal, to the Association of American Physicians, and the other by Dr. J. Nevins Hyde, of Chicago, to the American Dermatological Association. The disease in both cases originated in this country. Dr. Hyde's patient (*Jour. Cutan. and Gen.-Urin. Dis.*, 1896, XIV, 1) acquired it in the usual way; that is, by wading in rivers. It is a disease of slow but steady course, consisting in the appearance upon the foot of a large number of tubercles or fungoid nodules with fistulous canals leading under them down to a soft mass of tissue. The foot becomes swollen out of shape and useless. A puriform exudate, or one that resembles fish-roe, can be pressed from the tumors. It is an infective disease, due to an invasion of the tissues by the ray fungus. An excellent description of the microscopical appearances in the disease will be found in Dr. Hyde's paper.

At the last meeting of the American Dermatological Association one of the members proposed to give the name of "Pyodermia circumscripta superficialis idiopathica et traumatica" to what we have always called an "infected scratch." Our nomenclature is already overburdened, and there does not seem to be any need of a new name for so simple and self-evident a trouble as an infected scratch. There is small chance of the long and

unwieldy term ever being used, the name usually applied to the condition being all-sufficient.

In this connection the discussion over the terms leucoderma and vitiligo in a recent meeting of the New York Dermatological Society should be mentioned. Most writers on dermatology of recent times use the two terms indifferently; but at the meeting just referred to, Dr. Bronson, supported by Dr. Lustgarten, maintained that there was a distinction to be made between them; vitiligo being a definite disease, while leucoderma was only a condition that might be present in other dermatoses as well as in vitiligo. It seems better to drop either one or the other of these names, and to use the name achromia to designate the loss of pigment met with in so many diseases.

George Thomas Jackson, M.D.

ECHOES AND NEWS.

The *Medical Record* announces that the word *skiagraphs* [which, it will be remembered, was suggested by Dr. Catell in the Medical News of February 15th] is the best name that has been suggested for the Rontgen or X-ray pictures.

Dr. Nathan O. Harris, one of the most prominent physicians in Atlanta, Ga., died on March 6 from the result of an operation for appendicitis.

The Commissioners of Charity of New York city have asked the Legislature for an appropriation of $1,200,000 to be used in building a new morgue at the foot of East Twenty-sixth street, the erection of a Reception Hospital at Fordham, and the remodelling of the Almshouse buildings on Blackwell's Island.

The regular medical profession of Baltimore, Md., is somewhat indignant over the appointment of two homeopathic physicians to positions in the city medical service. The inmates of the jails will have to submit themselves to this practice or none.

The daily press brings reports of great cruelty to the inmates of Cuban hospitals by the Spanish troops. One hospital in Havana was first looted and then completely destroyed by them.

It is officially announced by the Medical Department of the University of Buffalo that its medical course, beginning with the session of 1896–7, will be extended to four years.

The directors of the New York Post-graduate Medical School and Hospital have named one of their wards in memory of the late Dr. Charles Carroll Lee, who was for many years a professor in the institution. They have placed a tablet in the ward, giving the names of those who combined to contribute the $10,000 which were given for the purpose of the memorial. The faculty of the institution participated largely in the memorial gift.

French scientists, who have been carrying on a series of experiments in regard to the vitality of microbes in books and on general printed matter, report that germs of various kinds were cultivated from the printed matter of books, and that the corners of pages where touched by the fingers yielded the most prolific results. It was shown that disease-bearing germs, such as those of diphtheria and erysipelas, retained their vitality and were capable of causing the dissemination of the diseases.

Dr. W. M. L. Coplin, professor of pathology at Vanderbilt University, Nashville, Tenn., has been elected to the chair of pathology and bacteriology in the Jefferson Medical College of Philadelphia, where until last year he occupied the position of adjunct professor of hygiene and demonstrator of pathology. The new pathological laboratory of the Jefferson will be completed by the opening of the next term, when Dr. Coplin will assume charge of this department.

The Craig Colony for Epileptics at Sonyea, N. Y., is about to be opened. The managers state that "an idea is gaining ground, not only in this, but in other States, that the State of New York is providing a large institution for the care of epileptics generally, and that all necessitous and dependent epileptics will be received and cared for. This is a grave error and should be early and earnestly discountenanced. Another growing misunderstanding is in regard to the reception of private patients in this institution. This is a feature entirely secondary in character, and is only to be entertained after all the dependent epileptics of the State have been provided for."

At a recent meeting of the New York State Board of Charities the secretary was instructed forthwith to notify in writing the individual managers of all institutions subject to the supervision of the Board, and having the care or custody of children, that corporal punishment upon such children is an abuse and an evil and must henceforth be abandoned.

The first number of the *State Hospitals Bulletin* is issued. It is to be a quarterly of 144 pages devoted to reports of clinical and pathological *data* in the several departments of the New York State hospitals for the insane, and under the management of the Lunacy Commission and the superintendents of the State hospitals. It is printed at the Utica State Hospital Print, and is published by the State. This number makes a very creditable appearance in every respect, but it remains to be seen how long the State will sustain any additional burdens in the care of its 20,000 insane other than what may be necessary for their mere subsistence.

The *Medical Record* announces that it completed its thirtieth year on Saturday, March 1st, the first number having been issued March 1, 1866. From the more extended experience of fifty-two years, the Medical

News extends its congratulations and encouragement to its still youthful but lusty contemporary.

An effort has been made by a committee of the New York County Medical Society and the New York County Medical Association to set aside the new appointments of visiting staffs to the various New York city hospitals under the reorganization by the Commissioners of Charities. The method of attack was to insist that these appointments came under the Civil-service law—requiring a competitive examination; and the matter was taken before a judge of the Superior Court. Judge Andrews has handed down his decision that the legislative act regulating the Civil Service did not intend that physicians should be subjected to the indignity of a Civil-service examination. He says: "The visiting and consulting physicians and surgeons, mentioned in the motion papers, are neither 'officers' nor 'employés' within the meaning of the so-called Civil-service acts. They receive no compensation; their positions, so far as pecuniary benefit is concerned, are purely honorary; and it is inconceivable to me that the Legislature should have intended that the most eminent members of the medical profession should be subjected to the indignity of an examination, either competitive or non-competitive, as a condition precedent to their being permitted to render gratuitious services in the hospitals which are under the control of the city. The objection that the defendants have delegated their appointing power is not tenable. They are under no legal obligation to select their appointees from the whole medical profession. They could appoint only those who had graduated from certain schools or who were of a certain age or who had had different kinds of experience; so they have a right to appoint those who have been nominated in the manner set forth in the motion papers if they see fit. Besides, they are under no legal obligation to confirm such nominees, and are at liberty to appoint others if they prefer to do so."

A Denver paper says the late Dr. Annie E. Marsh, of Greeley, Colo., bequeathed nearly all her property to the University of Michigan and her body to the University of Colorado. Her possessions included lands in Arizona, Colorado, and the East. Mrs. Marsh's husband carried out her desires as to the disposition of her body, which now lies on the dissecting-table. The University of Michigan, however, has received no intimation of the property bequest. Mrs. Marsh was for a long time a resident of Ann Arbor, and graduated from the medical department there.

At the request of Dr. Simon Baruch we insert the following correction of a typographical error occurring in the report of his paper in our issue of February 22d, 1896: "On the third line, second column, page 222, giving the mortality of pneumonia under the compress treatment devised by myself and under the usual treatment, the comparative number should be 12 per cent. under the water treatment to 77 per cent. under the ordinary treatment, instead of 12 per cent. to 17 per cent."

The legislative subcommittee of Maryland appointed to investigate her public institutions has avowed its intention to report unfavorably upon the condition of the Deaf, Dumb, and Blind Asylum of that State. When such committees are moved to disapproval there is usually good reason for their action.

The managers of St. John's Hospital, in Atlantic and Albany avenues, Brooklyn, one of the five institutions under the direction of the Church Charity Foundation, have made arrangements to open a school for trained nurses. It will be known as the Order of Trained Nurses. A rich friend of the hospital has furnished the money for the establishment of the school. The course will extend over three years.

Thirty-eight centenarians were recorded in Great Britain last year, fifteen men and twenty-three women. The oldest was Mrs. Henry, of Gortree, who died at 112, leaving a daughter of 9. In the last ten years the *St. James's Gazette* has kept track of 378 centenarians, of whom 143 were men and 235 women.

The secretary and a committee of members from the Illinois State Board of Health have gone to Chicago to examine the Dunham Medical College, and the American Medical Mission College of Chicago, with a view of ascertaining if their diplomas are eligible for recognition by the Board, as evidence of proficiency on the part of candidates for license to practice in that State. From Chicago the committee will visit Battle Creek, Mich., for a similar purpose.

By bequest of the late Mrs. Mary A. Grayden, of New York city, the sum of $6000 is donated to the Methodist Episcopal Hospital of Brooklyn, N. Y., and to the New York Home of the same denomination, in equal shares.

The following staff with their associates and assistants have been unanimously chosen by the Board of Trustees of St. Mary's Hospital, Brooklyn, N. Y., to serve for the ensuing year: Consultants—George R. Fowler, M.D., Jarvis M. Wright, M.D. Special consultants—Diseases of the nervous system, Landon Carter Gray, M.D.; diseases of the eye and ear, Arthur Mathewson, M.D.; diseases of children, Charles Jewett, M.D.; diseases of the skin, W. E. Griffiths, M.D. Consulting laryngologist—Jonathan Wright, M.D. Medical and surgical staff—Department of gynecology—John Byrne, M.R.C.S.(E.), president of the faculty; John C. MacEvitt, M.D., Walter J. Corcoran, M.D. Department of general surgery—John D. Sullivan, M.D., Charles H. Terry, M.D., J. C. Kennedy, M.D., Walter C. Wood, M.D. Department of orthopedic surgery—John C. Schapps, M.D. Department of general medicine—George R. Kuhn, M.D., secretary of the faculty; John Harrigan, M.D., J. S. Waterman, M.D. Department of nervous diseases—Lawrence J. Morton, M.D., R. S. Newton, M.D.

The medical report of the Adirondack Cottage Sanitarium at Saranac Lake, New York, for the past year states that of the 114 consumptive inmates treated,

twenty-one were apparently cured, in thirty-six the disease was apparently arrested, twenty-seven were apparently improved, twenty-seven were unimproved, and three died. Thirty-two patients were treated by injections of "modified" tuberculin, of which twenty-two were discharged. Of these nine were apparently cured, in eight the disease was arrested, two were improved, two unimproved, and one died from tubercular peritonitis. The list of contributors shows a widespread interest taken by the public in this commendable charity, and the financial statement bears evidence to efficient and economical management.

Dr. C. H. Tebault, of New Orleans, has been appointed Surgeon-general of the United Confederate Veterans, to fill the vacancy caused by the death of Dr. Joseph Jones.

Seventeen cases of diphtheria in Cecil County, Maryland, have been thought by the physicians in charge to be traceable to an infected cat. Attention also has been called to the supposed fact that nearly all stray cats and dogs are affected by one or more diseases which may or may not be communicable to mankind.

Dr. E. B. Delabarre, professor of psychology at Brown University, has been appointed successor to Dr. Munsterberg as director of the psychological laboratory at Harvard for 1896–7, and has accepted the appointment. He will not, however, be obliged to give up his work at Brown. The laboratory at Harvard is the finest in the country, if not in the world.

CORRESPONDENCE.

GLYCERIN EXTRACT OF BONE-MARROW.

To the Editor of The Medical News.

Dear Sir: In your issue of March 7th appears an editorial upon the therapeutic use of bone-marrow, in which the writer questions the value of glycerin as a solvent, and says that those persons who have had unsatisfactory results with marrow have used the medullary glyceride. So far as I can learn, there is but one other writer who takes this view of the case. On the other hand, there are a large number of physicians who have had the happiest experiences with the preparation originally advocated by Danforth.

Since I first used the glycerin preparation (considerably over a year ago) I have never had any bad results, and nothing worse than an occasional intestinal colic; and I have given it to many anemic and debilitated people with results that have been in every way gratifying. Of course there are poor preparations, for the process of maceration of the bones and extraction of the marrow is a laborious and slow one, and the temptation to manufacture weak products is very great.

Very truly yours,

Allen McLane Hamilton, M.D.

New York, March 8, 1896

THE HEARING ON THE ANTIVIVISECTION BILL BEFORE THE JUDICIARY COMMITTEE OF THE MASSACHUSETTS LEGISLATURE, FEB. 27, 1896.

[Special correspondence to the Medical News.]

The Massachusetts Society for the Prevention of Cruelty to Animals petitioned the Legislature to pass an "Act Relating to Vivisection in Schools" (House 548). A public hearing on the proposed bill was given by the Judiciary Committee of the House, Feb. 27, 1896, at 11 A.M. The following account is extracted from the stenographer's report. All unbracketed words are quoted directly. Great pains have been taken to state fairly all matters of importance.

J. A. Bailey, Jr., counsel for the petitioners (called attention to the existing act, chapter 151 of the Acts of 1894): The gist of that act is that no teacher shall practice vivisection in the presence of any pupils. We put in with our petition a somewhat elaborate bill, but we have changed our bill very radically. We come before you to-day with a simple bill in two sections.

An Act Relating to Vivisections in Schools.

Be it enacted, etc.

Sec. 1. Any agent or agents of the Massachusetts Society for the Prevention of Cruelty to Animals may be present at any experiment on or dissection of any *live* animal in any school or educational institution in this Commonwealth, and shall be permitted to witness the same; and the time and place of any such experiment or dissection shall, upon the request of any such agent, be made known to him by the person having charge of such experiment or dissection.

Sec. 2. Whoever violates this act by preventing any such agent from being present or failing to give any such agent information when requested, as above provided, shall be punished by a fine of not less than twenty dollars nor more than one hundred dollars.

George T. Angell, president of the Massachusetts Society for the Prevention of Cruelty to Animals: The law which we originally presented to you seems to us an eminently fair and proper one, but, on advice of counsel, and after consultation with various friends, we have concluded to drop three of its sections and confine ourselves to the other two. We are told through many articles in the public press and letters from students and others, the writers of which we are not at liberty to disclose, that there is much cruelty to animals in some of our medical and other schools. We simply ask that our agents—every one of whom shall, if desired, be furnished with a first-class certificate from his clergyman, or his lawyer if preferred, that he is a truthful man, of good moral character—may be present at these operations on *live* animals. (Witness now read extracts from the annual address before the Massachusetts Medical Society by Dr. Henry J. Bigelow, of which a fair idea may be given by the expressions: "Horrors of vivisection;" "Spinal marrow, the seat of all that is concentrated and exquisite in agony;" "The rumpled feathers of a pigeon deprived of his cerebellum may indicate not so much a specific action of the cerebellum on the skin as the more probable fact that the poor bird feels sick;" "My heart sickens as I recall the spectacle at Alfort in former times; a wretched horse

bound upon the floor and every conceivable and fiendish torture inflicted upon him, while he groaned and gasped;" "The limit of physiological experiment, in its utmost latitude, should be to establish truth in the hands of a skilful experimenter with the greatest economy of suffering, and not to demonstrate it to ignorant classes and encourage them to repeat it.")

(Witness then presented "a letter from a student" [Boston *Evening Transcript*, May 25, 1895], in which these words occur: "Then let it at once be known that it is the opinion of over four-fifths of the students of one of our largest medical schools that work in practical physiology on living animals is obnoxious, debilitating, and comparatively profitless; . . . not intensely interesting even to the earnest and scientific student is the sight of a small dog, weak with the loss of blood, running about the laboratory with a cork stopper in his neck. The object of this is to see how far they can carry certain experiments and have the dog still live.")

I do not know the name of this student, but I have given you his letter as printed in the *Transcript*. Gentlemen, we simply ask that the best agents we are able to furnish and employ shall have the privilege of being present wherever operations on live animals are performed, in order that we may satisfy ourselves that the laws for the prevention of cruelty to animals are not violated.

Cross-examination.—Q. What tests do you apply, if any, for the appointment of your agents? A. We select from the very best men we can get; for the last of those appointed we studied the list of the Boston police and selected a man. The captain said there was no better man on his force. We usually give some preference to men of experience in enforcing the laws. Q. But men of no scientific education? A. We can't afford to pay scientific men, you know; the dumb animals have not money enough to get very scientific men. Q. Do you take the ground that vivisection is unnecessary? A. I came here to say what these animals would say if they could talk. They would all vote against it to a man. Q. Are you familiar with experiments upon animals in these schools? A. No. Q. Are you yourself aware of any abuse or cruelty practiced on the animals? A. Only through reports and publications. Q. Your opinion, then, is formed on evidence which has been brought to you by published newspaper accounts? A. And by statements of students in medical schools and other persons. Q. Then you have never asked to be allowed personally to be present? A. No. Q. Have you evidence of specific acts of cruelty? A. I think some of these gentlemen have. I have invited certain gentlemen here who have expressed great sympathy. I don't know what they will say. Q. The purpose of the act is to select any agent, paid or unpaid? A. Yes. Q. This bill is promoted by the society or yourself? A. By the society, of course. Q. Has the society taken any action in regard to this bill? A. It has been brought before the directors. (In answer to repeated questions, witness was brought to say that the proposed bill was discussed at a directors' meeting, at which only seven out of the twenty-four directors of the society were present, and was "sanctioned" by the seven, including himself. Neither he nor Vice-President Hill could "remember whether any formal action was taken. The president had authority to take charge of the work of the society. The specific thing done here was done very largely under his general authority as president. A good many of the people who supported his society were intensely interested against vivisection. He supposed some would like to stop it and some would not, but he could not tell.") Q. Your expectation would be that you could get, if this bill were passed, such information that you could secure prohibition of vivisection? A. I will say that the dumb animals hope it would be prohibition. Q. Have you not published an offer of a reward for evidence of the abuse of the practice of vivisection? A. Yes, I have had a standing offer in *Our Dumb Animals*, which goes to almost every professional man in the State, an offer of $100 reward for evidence which will enable us to convict any man in Massachusetts of any violation of the law in the practice of vivisection. Q. Have you procured any? A. No. Q. If your agent reported that pain was inflicted in a certain experiment, would you consider that that report would be something to be acted on? A. The only question would be whether there was sufficient torture to the animals to warrant a complaint. The agent could report what he saw and heard, and it would remain with the judge whether he should grant a warrant or not.

Dr. Albert Leffingwell, of Cambridge: My experience as a physician and my experience in looking into this question convince me that vivisection has been of great service to humanity, and that, within limitations, there is no danger in its continuance. I believe in vivisection with certain limitations, but think it should be guarded against abuse; this bill is nonsense if there is no such a thing as abuse. (An extract was then read from an address by Dr. Parvin: "There are some who seek useless knowledge, and who seem to be blind to the writhing agony and terrible pain of their victims, and who are guilty of the most damnable cruelty. These criminals are not alone found in or confined to Germany or France, but may be found in our own country." Names were mentioned of physicians who favored the restriction of vivisection by law. Accounts of cruelty in Europe were given.)

Cross-examination.—Q. Do you feel that the agents of this society, with the qualification described by the president of the society, would be competent and a safe body to be the consors of the colleges of this Commonwealth? A. Not censors, but proper witnesses. Q. You have read some very harrowing descriptions of what goes on in Paris; tell us whether in your opinion that is a fair and just description of what goes on in Massachusetts? A. I am not personally acquainted with what happens in Massachusetts. I can't get into medical schools and laboratories. Q. Have you tried? A. No, I have tried in New York. Q. Have you tried in Massachusetts? A. No, it is said that no one would be allowed to go. Q. I understood you to say that unless there are abuses this bill is nonsense; have you any evidence of any abuse in Massachusetts? A. The abuses are simply these: that students are allowed occasionally

to practice vivisection on animals for their own purposes. I don't think it would be considered abuse by those having it in charge. Q. Are you sure that that is the fact? A. No, sir; only Mr. Angell says so. Q. Then I understand you have no evidence of any abuse? A. Not in this State; only that those doors are closed. Q. In your opinion could these experiments be properly conducted in the presence of agents of the societies? A. I think so; certain experiments could be. Q. Would that apply to all experiments? A. No; persons must exercise common-sense.

Mr. PHILIP G. PEABODY, president of the New England Antivivisection Society: I hold in my hand a list of physicians, I think several hundred, who are in favor of the abolition of vivisection. (Mr. Peabody here quoted several names therefrom.) The bill has been very carefully treated by those who have preceded me, and I will not spend any time upon that.

Cross-examination.—Q. Do you favor this particular bill or not? A. I do favor this bill, but I should like to have it altered so that the agents of the Antivivisection Society should be allowed the same privilege of witnessing the experiments as those of other societies. If the people of Massachusetts had the remotest idea of what vivisection really means, it would not be tolerated one month. I have seen vivisection in many instances, and I have never seen any anesthetics used. I think the anesthetics are for the public. Q. Have you observed those experiments in this State? A. I have never been permitted to observe them in this State. Q. Do you feel that a person who goes to see an operation with his mind all ready prejudiced against the whole question, a member of a society whose avowed purpose is to exterminate vivisection, is a proper man to go to such a place? A. Yes. (Witness now said in answer to questions, that he had been engaged in investigating these matters ten years, had published a good deal in the newspapers and elsewhere, and had got all the evidence bearing on this question that he could reasonably get.) Q. Have you any evidence showing any abuses in Massachusetts? A. Yes. Gentlemen come to my office almost every day and give me information concerning this, but say they don't want to be expelled from the school that they attend, as they would be if they were known to have stated these things. In a medical school in this State they take guinea-pigs in handfuls, two or three at a time, and crowd them into a vessel with a sponge of chloroform, and jam them down and put on a cover to the vessel, and sometimes the legs protrude and no pains are taken to put the legs in. (Witness declined to state where this occurred.) I have heard of many experiments performed without anesthetics. Q. Have you any other evidence? A. No. Q. You yourself have not seen any experiments on live animals in Massachusetts? A. No. Q. You were not permitted to? A. No. Q. Have you asked? A. I asked at the Harvard Medical School. (Witness being questioned further stated that six or seven years ago he had asked to see the experiments on animals, and was told none took place there. He did not know the location of the school, nor whether the person asked was an officer of the school. Thought that it was at the front door. Should say that the person asked was the janitor, not a professor. Had not been there since. Did not at that time represent the society, but went as a person interested in the subject. Could not remember that he had asked for the professor in charge of that department. Did not think he knew who the professor was at that time.) Q. Is that the only evidence you have on which to base your statements that you have been refused admission to these operations in medical schools in Massachusetts? A. Yes, the only personal evidence.

Dr. EUGENE W. HILL, of Newton. (Spoke in favor of the bill, though not opposed to vivisection. Thought that the bill would prevent unauthorized vivisection by students.)

Cross-examination.—Q. Have you any evidence that any abuses are practiced in Massachusetts in vivisection? A. Not in the laboratories; but I have been told that rabbits have been taken and tied up by the heels and hung out of the windows. (Witness said also that he had heard of students torturing guinea-pigs in barns.) If an agent goes into these laboratories he can tell very quickly those students who propose to go out and experiment by themselves. Q. How about this case you speak of—of students torturing guinea-pigs in barns; how could an agent help that; do you think he would learn in the school that a student was going to do such a thing in a barn? A. No, but I think he would learn the drift of the students' minds. Q. Does not the (existing) law provide for the suppression of this kind of cruelty? A. Yes, but it must be proved.

Mr. P. D. RICHARDS, of West Medford. (Not a physician; of no particular business. Spoke as a member of the community. Read from a manuscript so indistinctly that he could not be reported. He was understood to relate cruelties practiced in Europe, and to attack professors in the Harvard Medical School because of their alleged misrepresentation of facts. He spoke of persons in Ohio who had petitioned the legislature to permit vivisection of criminals. The vivisectors would be after paupers and babies next; babies because they were easy to handle.)

Cross-examination.—The CHAIRMAN: Are there any questions to be asked of this gentleman? (Silence of several minutes.) Mr. RICHARDS: No questions? Perhaps it is just as well that they don't ask me any questions about the Harvard Medical School or the Boston University. Q. You have something to say about the Harvard Medical School? A. I can tell of the open doors which Dr. W. T. Porter speaks of in his letter. (Replying to various questions, witness stated that he had applied for permission to be present at vivisections in the Harvard Medical School, and had been referred to the dean. On writing the dean, a secretary replied that he was in Europe and referred him to some one else, who, when witness wrote, had also gone to Europe. Had written also to the Boston University, and to Gen. Walker at the Institute of Technology. The Boston University had replied "that the doors were not open to morbid curiosity." Gen. Walker had answered

"that we were not competent to inquire into the matter and were not permitted to go there.") Q. What reason did you state in any of those letters for wishing to visit the laboratories? A. I can't say, but they could naturally infer from my articles in the papers that it was for inquiring into cruelties. Q. Are you acquainted with Dr. Richardson or Dr. W. T. Porter? A. Yes, sir. He lied to me; they all lie: all that I have met; all of them lie. Q. What are your grounds for arraigning these doctors simply because they did not want to gratify a morbid curiosity? Don't you think in the case you have stated it was a proper refusal? A. No. I met with no refusal in Cambridge, and no honest person would be refused. Q. The man who invited you knew something personally of you? A. Yes. Q. Doesn't that make an entirely different case, where a man knows the person who makes the application for such a privilege? A. Yes. Q. You are an opponent to vivisection in any form? A. Yes, a strong opponent. Q. And in the same way you are opposed to vaccination? A. Yes, I am opposed to that. Q. How many times have you been to the Harvard Medical School? A. Three or four times, including the stock-room for housing the animals. Q. How did you happen to go in there? A. I was passing the alleyway and saw them going in, and I took the opportunity to go in. I followed the cart. I went in like a man. Q. At that time you went in the back door, and after that went to the front door? A. Yes. Q. You met Dr. Porter, did you not? A. Yes. Q. And had a long conversation? A. Yes. He said they only used curs in their experiments, but immediately after that one of the students told me they used Newfoundland dogs.

Mr. Bailey, Counsel for petitioners: I wish to say that counsel regrets keenly that any epithet should have been applied to so honorable a body of gentlemen as the instructors of the Harvard Medical School.

Mr. Winslow W. Fifield, of Malden: I am in the real-estate business and have been for years, and am also a justice of the peace. I am a friend of the dumb animals. Mr. Bailey: Do you wish to testify to any facts known to yourself or on information given you? Witness: No, I do not, only I speak for the dumb animals. I would be one to contribute to a fund which should be used to employ Prof. Garner to go into the kennels of Massachusetts and learn the language of the animals there. The Chairman: We cannot go as far as that. (No questions were asked this witness.) Mr. Bailey: I think we will rest here. The Chairman: Then at the next meeting we will hear the remonstrants to the bill.

Another wing to the Free Hospital for Women, situated at Brookline, Mass., was opened last week with appropriate ceremonies.

The Culles' Home for Consumptives, of Boston, Mass., is meeting with great opposition from residents in the vicinity of its proposed location. The selection of Grove Hall has aroused objections, not only from those living near, but also from the park commissioners of that city.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynecology.

Stated Meeting, Feb. 27, 1896.

W. R. Pryor, M.D., Chairman.

THE INDICATIONS AND SURGICAL TREATMENT OF RETRODISPLACEMENTS OF THE UTERUS.

The discussion was introduced by three papers: The first by Dr. Mundé (see page 281), presenting the indications for the Alexander operation; the second by Dr. Edebohls (see page 282), treating of ventral fixation; and the third by Dr. Vineberg (see page 287), advocating vaginal fixation.

DISCUSSION.

Dr. Noble, of Philadelphia, said that if he looked at the subject solely from the point of view of the gynecologist, he would prefer suspensio uteri as being both safe and efficient, but from the standpoint of the obstetrician not so much could be said in favor of the operation. He had met with two cases in which serious distocia had resulted from the obstruction produced by the uterus at the pelvic brim after this operation. In one of these cases it had been necessary to do a Porro operation. As he was now engaged in collecting statistics regarding the complications of pregnancy and labor which follow ventral fixation, he would for the present suspend judgment. He thought any surgeon should be able to do Alexander's operation, particularly if he adopted the plan of opening up the inguinal canal. In certainly 90 per cent. of the cases ordinarily demanding a ventral fixation, the patients were over 40 years of age, so that it could hardly be said that the question of the effect of the operation on a possible subsequent pregnancy played a very important part. A very slight attachment of the uterus to the abdominal wall by sutures might give more favorable results. He had not been able as yet to see the advantages of vaginal fixation.

Dr. H. J. Boldt said that the operation *par excellence* for cases of retrodisplaced but mobile uterus was that of shortening the round ligaments. At one time he had thought quiet favorably of the operation of vaginal fixation, but now in the very class of cases in which he had formerly advocated vaginal fixation he preferred to do Alexander's operation. In cases of firm posterior adhesions, an effort was sometimes made to break up these adhesions and then shorten the round ligaments, but he felt that it was doubtful if these adhesions were usually broken up with sufficient thoroughness to allow of the uterus remaining permanently in the anterior position: hence in such cases he preferred to do a ventral fixation. Although in two of his cases one of the round ligaments had broken, the remaining one had proved equal to the task of maintaining the uterus in good position. No definite rule could be laid down regarding the number of inches that the round ligaments should be shortened; usually the ligament was shortened until the horn of the uterus appeared at the internal ring.

Dr. Ill said that in his opinion Alexander's operation

was indicated in all cases of retrodisplacement of the uterus in which, for any reason, treatment by a pessary was ineffectual. He had done about ninety ventral fixations, and had not seen a case of hernia following this operation. Three of his patients had afterward passed through pregnancy without any complication. He had been informed that fifteen cases of hernia, due to the operation of shortening the round ligaments, had been operated upon last winter at the Hospital for Ruptured and Crippled.

Dr. J. Riddle Goffe said that it had been his practice until recently to treat cases of retroversion, with or without adhesions, by shortening the round ligaments. Where there had been adhesions he had first opened Douglas' pouch and broken up these adhesions before shortening the ligaments. The only objections to this treatment had been the unpleasant scars, and he thought even this difficulty could be removed by resort to vaginal fixation. From what experience he had already had with the latter operation he was willing to assert that it accomplished an anatomical cure in a very satisfactory way, but, of course, one could not deny that the reports from abroad regarding the effect in subsequent pregnancies was rather discouraging. As the anterior vaginal wall was invariably shortened in cases of long standing retroversion, thus interfering with throwing the cervix backward into the hollow of the sacrum and allowing the fundus to come forward, he had adopted the transverse incision.

Dr. E. B. Cragin said that during the last few months he had done fifteen vaginal fixations, but he had met with a number of failures, and had not been very favorably impressed with the operation. In the future he would probably perform it only as a supplement to work already done by the vaginal route.

Dr. A. Palmer Dudley said that he did not think Alexander's operation was indicated unless the surgeon could feel sure that not only the uterus but the appendages were non-adherent and not diseased. If there were doubt on this point—and there was very apt to be—he would prefer to perform abdominal section and determine the actual condition present. In performing ventral fixation he did not consider it necessary to insert salmon-gut sutures—indeed, it was not the sutures that kept the uterus in its anterior position, but the action of the weight of the abdominal organs after the uterus had been placed anteriorly. If, after breaking up the adhesions through an incision in the cul-de-sac the uterus was restored to proper position, it could be held there by proper gauze packing without further operative measures.

Dr. H. L. Collyer said that in many cases of pregnancy occurring after Alexander's operation the ligaments had been ruptured or a miscarriage had resulted. He had followed three cases of hysterorrhaphy in which abortion had resulted from the uterus being unable to rise up out of the pelvis. It seemed to him that vaginal fixation was the best of the operations under discussion.

Dr. Joseph Brettauer said that he had been inclined to think that, although vaginal fixation was not ordinarily indicated, it might prove useful in cases of congenital retroversion, but Dr. Vineberg had stated this evening that it was in just this class that vaginal fixation was contra-indicated.

Dr. C. B. White favored Alexander's operation in cases of backward displacement or prolapse in unmarried women; but if the tubes and ovaries were diseased, it might be better to shorten the round ligaments by opening the abdomen.

Dr. A. E. Gallant referred to the pain sometimes experienced after too great shortening of the round ligaments.

The Chairman said that he believed that if there were no adhesions these cases could be cured by plastic operations alone. Following in the lead of Dr. Henroten, of Chicago, he had recently been doing some surgery through the cul-de-sac, and felt that he had obtained some cures in this way. Of the three operations under discussion, he preferred the Alexander operation, because it raised the uterus at the same time that it placed it anteriorly.

Dr. Edebohls said that on theoretical grounds he could not see that modifications of the method of operating should materially affect the result, because it was beyond our power to control the strength of the peritoneal adhesions that formed. Of the three operations, Alexander's was the only one which left the uterus free and unattached by peritoneal adhesions. There was nothing on record to show that after Alexander's operation there was any trouble in subsequent pregnancies. As much could not be said for the still very young operation of vaginal fixation.

Dr. Vineberg said that he desired to correct an impression that seemed to exist regarding Mackenrodt's operation. Mackenrodt certainly had not abandoned the operation which bears his name, for in his very last paper he refers to various favorable opinions that had been expressed regarding it by certain eminent surgeons abroad. He had only changed the technique. The speaker said that recent statistics showed that there was quite a large percentage of failures after Alexander's operation, and that the mortality was as high as 5 per cent. He felt that enough emphasis had not been laid upon the great danger of hernia after this operation, or after the operation of shortening the round ligaments by opening the abdomen. He could not but think that it was not good surgery to open the abdomen and produce one weak point, and then do an Alexander's operation, thus making two additional weak spots.

SOCIETY MEETINGS.

THIRD INTERNATIONAL CONGRESS OF DERMATOLOGY.

To be held in London, August 4th to 8th, 1896.

PROGRAM.

Tuesday, August 4th—Preliminary Business.

12.00 M. Presidential Address.
3 P.M. Subject: "Prurigo."
1. Dr. Besnier (Paris).
2. Prof. Kaposi (Vienna).
3. Dr. J. C. White (Boston).
4. Dr. Payne (London).

WEDNESDAY, AUGUST 5TH.

9.00 A.M. Clinical Demonstration of Cases.

DERMATOLOGY.

10.30 A.M. Subject: "The Etiology and Varieties of Keratosis."

1. Dr. Unna (Hamburg).
2. Dr. H. G. Brooke (Manchester).
3. Prof. V. Mibelli (Parma).
4. Dr. W. Dubreuilh (Bordeaux).

3 P.M. Papers.

SYPHILIS.

10.30 A.M. Subject: "Syphilitic Reinfection."

1. Prof. Fournier (Paris).
2. Prof. Lang (Vienna).
3. Mr. Alfred Cooper (London).
4. Dr. Fitzgibbon (Dublin).

3 P.M. Papers.

THURSDAY, AUGUST 6TH.

9 A.M. Clinical Demonstration of Cases.

DERMATOLOGY.

10.30 A.M. Subject: "The connection of Tuberculosis with Diseases of the Skin other than Lupus Vulgaris."

1. Dr. J. Nevins Hyde (Chicago).
2. Dr. Hallopeau (Paris).
3. Dr. Radcliffe Crocker (London).
4. Dr. G. Riehl (Vienna).

SYPHILIS.

10.30 A.M. Subject: "The Duration of the Period of Contagion of Syphilis."

1. Mr. Hutchinson (London).
2. Prof. Campana (Rome).
3. Prof. Lassar (Berlin).
4. Dr. Feulard (Paris).

2.00 P.M. Subject: "Ringworm and the Tricophytons."

1. Dr. Sabouraud (Paris).
2. Prof. Rosenbach (Gottingen).
3. Mr. Malcolm Morris (London).

Many contributions to this debate promised.

FRIDAY, AUGUST 7TH.

9.00 A.M. Clinical Demonstration of Cases.

DERMATOLOGY.

10.30 A.M. Subject: "The Nature and Relations of the Erythema-multiforme Group."

1. Prof. de Amicis (Naples).
2. Dr. T. H. Veiel (Stuttgart).
3. Dr. P. A. Morrow (New York).
4. Dr. Stephen Mackenzie (London).

SYPHILIS.

10.30 A.M. Subject: "Malignant Syphilis."

1. Prof. Handlung (Copenhagen).
2. Prof. Neisser (Breslau).
3. Prof. Tarnovsky (St. Petersburg).

2.00 P.M. Clinical Demonstration of Cases.

DERMATOLOGY.

3.00 P.M. Papers.

SYPHILIS.

3.00 P.M. Papers.

SATURDAY, AUGUST 8TH.

9.00 A.M. Clinical Demonstration of Cases, followed by Papers.

NOTE.—The Congress has been fortunate enough to secure for its use the building known as Examination Hall, on the Victoria Embankment. This will afford every facility for all kinds of demonstrations: cases, pictures, museum, etc. Special efforts are being made to have large clinical demonstrations of cases, and all who have been in London know how rich is the material there. It is of the greatest importance that those intending to join the Congress should notify the Secretary, Dr. J. J. Pringle, 23 Lower Seymour street, London, W., of their intention as soon as possible. The membership fee is $5, which should be sent in the form of a one-pound sterling draft on London, or P. O. order to the same amount.

GEO. THOS. JACKSON,
14 East 31st street, New York,
Secretary for the United States.

PRELIMINARY PROGRAM OF THE ANNUAL MEETING OF THE TRI-STATE MEDICAL SOCIETY.

To Be Held in Chicago, April 7, 8, and 9, 1896.

Dr. Nicholas Senn, Surgical Clinic; Dr. John B. Murphy, Surgical Clinic; Dr. J. H. Etheridge, Gynecological Clinic; Dr. F. Henrotin, Gynecological Clinic; Dr. J. M. Mathews, Louisville, public address; Dr. J. J. M. Angear, Chicago, subject unannounced; J. R. Ash, Brighton, Ill., subject unannounced; Frank Allport, Minneapolis, subject unannounced; Wellington Adams, St. Louis, "A New and Practical Method of Opening and Dilating the Eustachian Tube"; J. J. Brownson, Dubuque, Ia., "Chest Drainage in Empyema"; J. M. Ball, St. Louis, "Eye Symptoms in Brain Tumor"; G. W. Barr, Quincy, Ill., "The Use of Patent Medicines"; G. Wiley Broome, St. Louis, "The Diagnosis and Surgical Treatment of Cancer of the Cervix"; D. C. Brockman, Ottumwa, Ia., "Points in Surgical Practice"; A. H. Cordier, Kansas City, "Pregnancy Complicated by Cancer of the Cervix—Report of Case"; G. W. Cale, St. Louis, "Surgical Treatment of Brain Tumor"; F. B. Dorsey, Keokuk, Ia., "Fracture of Pelvis, Complicated with Pregnancy"; L. H. Dunning, Indianapolis, subject unannounced; C. Travis Dreneen, Hot Springs, Ark., "Gonorrhœal Rheumatism"; H. C. Eschbach, Albia, Ia., "Colles Fracture"; R. C. Heflebower, Cincinnati, "Foreign Bodies in Crystalline Lens" and "The Ophthalmoscopic Findings in Reynaud's Disease"; Webb J. Kelly, Galion, O., "The Treatment of Unreduced Fractures of the Lower End of the Radius"; Emory Lanphear, St. Louis, subject unannounced; Merrill Rickets, Cincinnati, "Anal Fistula; Peritonitis; Laparotomy; Recovery"; Adolph Meyer, Worcester, Mass., "Etiological, Clinical, and Pathological Factors in Diagnosis and Rational Classification of the Infectious and Toxic Diseases of the Peripheral Nerves, Spinal Cord, and Brain"; C. B. Nancrede, Ann Arbor, Mich., "The Operative Treatment of Jacksonian and Focal Epilepsy as Illustrated by Selected Cases"; Paul Paquin, St. Louis, "Some Recent Criticism on the Serumtherapy"; Roswell Park, Buffalo, N. Y., "Auto-infection in Surgical Cases"; J. F. Percy, Galesburg, Ill., "Special Education as a Means of Treatment in Chronic Neurasthenia"; John Punton, Kansas City, subject unannounced; F. Reder, Hannibal, Mo., "Remarks on a Partial Dislocation of the Axis"; D. S. Reynolds, Louisville, "Local Treatment of the Eye"; R. Harvey Reed, Columbus, O., subject unannounced; E. O. Sisson, Keokuk, "Ulcerative Inflammation of the Cornea"; T. O. Summers, St. Louis, "Leucocytosis: Its Relation to Modern Therapy"; W. W. Wathen, Louisville, "Pathology of Cystic Tumors of the Ovary and Broad Ligaments"; O. B. Will, Peoria, "Dysuria in the Female"; Alex. Hugh Ferguson, Chicago, "Pylorectomy in America"; D. R. Brower, Chicago, "Anemia and Its Relation to the Nervous System, with Suggestions as to Treatment"; John Ridlon, Chicago, "Flat-feet"; J. B. Bacon, "Conservative Surgery in the Treatment of Hemorrhoids"; Weller van Hook, Chicago, subject unannounced; Wm. Allen Pusey, Chicago, subject unannounced; Arthur Edwards, Chicago, subject unannounced; Frank Billings, Chicago, subject unannounced; Gustav Fuetterer, Chicago, subject unannounced; T. J. Shuell, Parnell, Ia., "The Relation of Fecal Impaction to Appendicitis"; Dr. Otto Sutter, St. Louis, subject unannounced; Dr. A. E. Mink, St. Louis, subject unannounced; Dr. G. H. ORIGINAL ARTICLES.

SPORADIC CRETINISM, WITH REPORT OF A CASE TREATED WITH THYROID EXTRACT.

BY H. H. VINKE, M.D.,
OF ST. CHARLES, MO.

UP to within recent years the object of the thyroid gland in the human economy was not understood. Bruecke, in his excellent work on physiology, tells us that not even an hypothesis had been advanced as to the function of that organ. It was thought that the thyroid body might be entirely excised, or completely disorganized or destroyed by some morbid process, without any noticeable changes or harmful results occurring. The failure of the older observers to determine the function of such an important organ may have been due to the circumstance that in their experiments they failed to entirely excise the gland, or to the fact that the characteristic disturbances after excision appear late, not until the secretion, stored in the system, has been exhausted. The relation between the late symptoms and the ablation of the gland may have been lost sight of for that reason. The brilliant researches of Schiff, Horsley, and Murray were rewarded with better results, however, and the profession is indebted to these patient and careful investigators for all that is known of the function of the thyroid gland. They showed conclusively that this gland plays a momentous rôle in normal metabolism—the power living cells possess of appropriating, from the ultimate products of digestion brought to them, those substances essential to their growth and development into maturity, and of maintaining their individuality after arriving at maturity. It was further proved by Ord, Kocher, and others that the symptoms resulting from an extirpation of the thyroid gland are identical with those of myxedema, a disease that was accurately described as early as 1873, but of the cause of which nothing was known. The inference that surgical myxedema, or cachexia strumipriva, was dependent upon the same cause, namely an absence or complete disorganization of the thyroid body, was but natural and unavoidable. Ord was the first one to call attention to the fact that cretinism is but a congenital form of myxedema. The great Brown-Séquard, the father of organotherapy, long since has shown that diseases arising from a lack or an absence of the normal secretion of a certain gland might be successfully treated with the healthy juice of that organ obtained from lower animals; but it remained for Horsley, Schiff, and Murray to first demonstrate the marvellous healing power of the thyroid juice in myxedema. Horsley and Schiff first proposed the treatment of myxedema and cretinism by the grafting of the sheep's thyroid; Vasale then used intravenous injections of thyroid juice; and Murray, injections of a glycerin extract of the gland. The experiments of the latter attracted by far the most attention, and were most instrumental in acquainting the medical profession with the extraordinary effects of thyroid-feeding in myxedema and cretinism. Howitz was the first to give thyroid extract by the mouth; and, as this is a very effective and convenient form of administering it, it is now in general use.

Those interested in this subject should not fail to read the valuable paper on the "History of the Thyroidtherapy," by Dr. S. J. Metzger, in *The New York Medical Journal* for April, 1895, from which I have drawn, and who gives a much more complete history of the evolution of thyroid-feeding than I have attempted. Like most discoveries in medicine, our knowledge of the function of the thyroid gland, of the disastrous results of disturbed or annihilated function and of the proper and specific remedy for the relief of those disturbances, was gained by experiments on lower animals. The researches of Ord, Kocher, and others resulted in establishing the identity of myxedema, cachexia strumipriva, and cretinism. The close relation existing between goitre and cretinism has long been suspected, cretinism being of frequent occurrence in those countries or districts in which goitre is rampant. The benign, parenchymatous goitre is of course here alluded to, and it is now thought that simple parenchymatous enlargements of the gland are the effect of an extra effort on the part of the gland to supply the system with sufficient normal secretion. In Dr. Ashmead's opinion cretinism is but the consequence of goitre. To his mind both diseases are evidences of the approaching extinction of

the human race, the closing act in the drama of human life, ushered in with goitre and brought to a gloomy close by cretinism. Opinion has been advanced that exophthalmos is the result of hyperthyroidization, or excessive secretion; and this supposition seems to be supported by the fact that by feeding myxedematous patients too large amounts of the thyroid juice, symptoms not unlike those of exophthalmic goitre are produced.

Cretinism might be defined as being a disease characterized by profound disturbances in nutrition, resulting in arrest of growth and development of body and mind, the characteristic changes in the body finding expression in a stunted and dwarfish stature and general tumefaction of the skin, those of the mind in imbecility, or even idiocy. The etiology of this disease is a varied one. It is endemic in certain mountainous regions, as the Alps, Pyrenees, Vosges, Jura, and certain districts of Central and South America. Sporadically, it is met with in nearly all countries of the globe. It has been stated that cretinism is endemic in the valleys of Vermont, Massachusetts, and California; but as an evidence of the rarity of this disease in North America, it is only necessary to refer to the circumstance that Osler,[1] in his exhaustive monograph on this subject, found that up to 1893 only eight cases had been reported in this country. Since then cases have been reported by Crary,[2] Lloyd,[3] Townsend,[4] Mills,[5] West,[6] Sinkler (two cases),[7] Fruitnight and Brown.[8] The case here related is, as far as I know, the first one treated in the West.

Altitude has been thought to play an important part in the etiology of cretinism, but cretins are found in valleys as well as in mountainous regions. Water rendered impure by an excess of magnesia, glacier water or snow-water imbibed before it has become well aerated, have been thought of as causes in the production of this disease, but cretins are found in regions where the inhabitants never drink snow or glacier water, and where it does not have an excess of magnesia or lime. Inasmuch as cretinism occurs under such varying circumstances, it may be possible that some specific *materies morbi* is responsible for its production. In-and-in-breeding, lack of sufficient and proper nourishment, and other agents that lessen the individual's power to resist disease in general will no doubt also increase tendency to cretinism. The disease may begin early or late in intra-uterine life, but usually makes its appearance between the second and fifth years.

The symptoms of this disease are so characteristic that they cannot readily be mistaken, and are clearly defined in the report of my case.

The administration of thyroid extract or juice, obtained from healthy thyroid glands of lower animals, preferably sheep's thyroids, constitutes the sole effective treatment of this rare disease. It is thought that the active principle in these thyroids is a nucleo-albumin,[1] but I do not know whether manufacturing chemists have been successful in separating this proteid from the thyroid gland.

Our little patient was first seen by me on the 2d of September, 1895, and his appearance was so characteristic that no difficulty was experienced in arriving at the diagnosis of cretinism. He was born in Missouri, close to the mouth of the Missouri river. Parents are not blood-relations. The father is healthy, 38 years of age, and immigrated from Baden, Germany. The mother is about 35 years of age, was born in this State, and has been in perfect health up to about seven years ago, since which time she has had occasional attacks of epilepsy, or seizures simulating that disease. The patient has four sisters, 10, 7, 4, and 2 years, respectively; two brothers, aged 8 years and 8 months, respectively; they are all healthy and well developed. One brother died in childhood as a result of some fever. Our patient was born 6 years ago. The labor was slow and tedious, lasting three days, but no instruments were used. The mother is certain that the period of gestation was in this case prolonged, lasting ten months. The child was born with an extraordinarily large head, large, broad face, thick lips and tongue. The mother noticed at once that its voice was different from that of the other children. Physical and mental development was slow. Was not playful like other children, took little interest in his surroundings, and could only with difficulty be made to laugh or notice things. He was 19 months old before he could stand up. The child grew thicker and gained but little in height. The limbs became crooked, fat, and clumsy; he slept much and ate but little. The mother tells us that the fecal discharges of this child were always peculiar; they were large in volume, large in quantity, and hard.

From the above history it is evident that the child came into the world stigmatized with the unmistakable marks of cretinism; and if the mother's statement as to the duration of the period of gestation is correct, it would seem that *in utero* even the development of these cretins is slow and abnormal, and that they require a longer

time to arrive at a viable age than normal children. My notes at this examination describe the following state of affairs: Though 6 years of age, the little fellow is of the height of a child aged about 2 years. He has an enormous head, covered with a heavy, dirty layer of dandruff. The anterior fontanelle is as yet not closed. The expression is characteristic of cretinism; he looks very stupid, almost idiotic. His face is broad; nose flat and turned up; face and lips much swollen; tongue, also, much enlarged, and most generally protrudes from the mouth. Neck short and thick. The entire body and the extremities much swollen, and he presents an appearance not unlike that of an extremely fat baby. Arms and legs, as well as the fingers and toes, are short and

Fig. 1.

(From a photograph when first seen.)

plump. The skin over the entire body, instead of being natural, soft, and warm, is firm, cold, hard, and unpliable, and is never moist with sweat. There is no pitting upon pressure. The abdomen is enormously enlarged. Percussion and palpation do not reveal any enlargement of the liver or the spleen. Resonance is tympanitic over entire abdomen, as if stomach and intestines were distended with gases.

A side view shows marked lordosis, most prominent in lumbar region. The testicles have not descended into the scrotum; scrotum and penis small. The joints are somewhat thicker than usual and stiff. Legs are markedly curved; he walks with difficulty, and in an uncertain tottering manner, and falls readily when knocked against. The head, as already stated, is covered with a thick, dirty scum, which the mother is unable to wash away; the hair is stiff and scant, and lacking usual lustre. He walks but little; can say a few words intelligently, in an intelligible manner, and only his parents can understand what he wants. But his wants are but few, and he is always good-natured and still. He sleeps a great deal; goes to bed early, and usually sleeps until noon next day. His voice is coarse and unnatural. There is no difficulty of deglutition, but swallowing is accompanied by a peculiar gurgling noise. Dyspnea is rarely present, and never very marked. Dentition was delayed, but teeth fairly good. Hearing, taste, and smell appear to be normal. Heart normal; pulse 110 per minute; temperature slightly below normal. He never had convulsions; never suffered with hemorrhages from mucous membranes; no fatty tumors are found in the supraclavicular region. The thyroid gland appears to be absent; at any rate, we are unable to find any evidence of same. The accompanying photograph, No. 1, and the measurements taken at this examination, will show the exact condition of our patient at this time.

Such was the mental and physical condition of our patient. The diagnosis of cretinism was therefore an easy matter, and thyroid-feeding at once suggested itself. I called in Dr. J. H. Bruere, of this city, who agreed with me as to diagnosis and treatment. I also consulted Prof. Frank P. Norbury, of St. Louis, who advised the use of thyroid extract. I am greatly indebted to Dr. Norbury for many valuable suggestions as to the proper treatment of these cases, and of measures tending to improve the mental as well as physical condition of the little fellow. Immediately upon the exhibition of this remedy he began to improve, and at the close of the first week a decided decrease in weight was observed. The loss of weight was most marked during the first six weeks of treatment, and at the end of the first two months he had lost twenty-two pounds. He had gained over an inch in height. At this time I again had the boy photographed, and took measurements, which will be found at another place. The face and lips were much thinner, the legs were straight, the stature more erect, and the entire body much thinner. The skin was soft, warm, and natural. When coming to my office he had walked a distance of five blocks, which he had never done before. The anterior fontanelle was nearly closed, the hair soft and natural. The gurgling noise, when swallowing, was absent, and his voice was natural. His mental condition, too, had much improved. He is now much brighter. He can say entire sentences in an intelligible manner. He takes a lively interest in his surroundings, and delights to play with other children. But he has lost his good-natured disposition; is easily irritated. He does not sleep more than other children, and is an early riser. He has now an enormous appetite, though constantly losing

weight. To the mother it seems that the head is sunken in; that the neck is longer and the joints more supple. In one word, his general condition, physical as well as mental, has considerably improved; his appearance, however, remains markedly cretinoid (Fig. 2) The photograph and measurements taken at the last examination a few days ago, and five months after the beginning of treatment, show a decided improvement in the general condition of the little fellow. In fact, the change is most remarkable. He now has a healthy appearance. The face has a much more intelligent and natural expression. The edema of the skin and subcutaneous tissues has disappeared. The skin is soft and warm. An abundant growth of soft and natural hair covers the

FIG. 2.

(From a photograph five months later.)

head. The anterior fontanelle is closed, and all dandruff scales have disappeared. The lordosis and the prominence of abdomen are scarcely noticeable. His legs are straight, and he can now walk several miles without becoming fatigued. But for his age he is still very small, and rather clumsy in his walks and movements, and, also, intellectually he is considerably behind children of his age. But the splendid results obtained by Osler, Sinkler, Starr, Crary, West, and Lloyd, in this country, and a number of observers abroad, justify the expectation that this little patient, too, will entirely recover, and attain the somatic and mental condition of an ordinary normal child.

It will be observed that the loss in weight was most marked during the first two months, and continued until the patient had lost 24 pounds at the close of the third month, when he began to gain; the increase in height, of course, continued, and amounted to four inches in five months. During these five months he has taken uninterruptedly ½ grain of Parke, Davis & Co.'s Thyroid Extract three times a day. As no ill effects resulted, and as this amount seemed to act splendidly in our case, the dose was neither increased nor diminished. It has been pointed out by other observers that cretins bear thyroid extracts particularly well, and symptoms of thyroidism do not occur in these patients nearly as readily as in acquired or surgical myxedema. Thyroid extracts have been recommended of late in obesity, goitre, and in exophthalmic goitre. The rapid loss of weight, following the exhibition of thyroid extracts in a large number of cases of obesity, would seem to show that a lack of normal thyroid secretion is a prominent factor in the production of obesity, and that the judicious administration of thyroid extracts supplies this want. In recent years thyroid extract has been much employed by W. O. Taylor, Bruns, Kocher, and others in cases of simple benign goitre, and the results of this treatment have been found entirely satisfactory. In the young, particularly, thyroid-feeding is usually followed by a rapid decrease in the size of the tumor, or complete disappearance of the goitre. A cessation of treatment, however, has been followed by a return of the goitre. Thyroid juice has also been recommended in exophthalmic goitre, a disease which, it is now held, results from excessive thyroidization. Most observers, like Auld,[1] Eulenberg, Dr. H. W. Herman, of St. Louis, and others, have found that all the distressing symptoms of exophthalmos are aggravated by the administration of thyroid extracts, while Voisin[2] claims excellent results for the treatment.

These varying results, however, are not so much at variance as they would seem to be at first glance. As is well known, continued morbid or excessive functional activity of a gland will eventually result in structural disorganization and total arrest of function. Hence it might be conceived that at one time the administration of the thyroid extract would be absolutely harmful; at another and later time, of decided advantage. There can be no doubt, however, as to the efficacy of thyroid-feeding in cretinism and other forms of pachydermic cachexia. In fact, it is the unanimous verdict of those who have had an opportunity to witness the marvellous changes wrought in these patients, that there are few diseases so amenable to treatment as cretinism, and few remedies more effective than thyroid extract.

WHAT IS THE VALUE OF OPERATIVE INTERFERENCE IN THE TREATMENT OF EPILEPSY?—BASED ON AN ANALYSIS OF SEVENTY CASES TAKEN FROM CONTEMPORANEOUS LITERATURE.[1]

By EDWIN GAILLARD MASON, M.D.,
OF NEW YORK CITY;
LECTURER ON MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC.

When we consider the rapid advances that have been made in surgery and localization in the past few years, we cannot wonder that the brain has been invaded in a search for the cure of epilepsy, that *bête noir* of practitioners of medicine from the very earliest time of which we can trace any record of medical matters. Again, when we think of the almost indefinite number of drugs that have been given empirically from time to time,—some of them worse than useless, others of undoubted value,—and how wide this disease has opened the door to quackery and charlatanism, we wonder even less that the poor sufferers have overcome the instinctive dread of the knife and turned to the surgeon, asking him to do what in his judgment he thought best. The zeal with which skulls of epileptics were attacked a few years ago, when the advent of antiseptic surgery and experimentation in localization, almost simultaneously, forced themselves so vividly upon our minds, has had its counterpart in other branches of medicine, notably the several "cures" for consumption, which startled the world for weeks or months and then disappeared. This comparison, however, is hardly fair, for operation for the cure of epilepsy (and in this paper I will limit the meaning of operation chiefly to trephining) is a rational procedure, and has come to stay; though that it has been very much overdone, or rather that it has been done ill-advisedly and that the cases for operation have been selected with very bad judgment, cannot be successfully denied. Happily a reaction is now beginning to set in. Any one who has had occasion to look up the literature of the past ten years must be struck by the difference in the tone of the reports of eight and ten years ago as compared with those of the last eighteen months. Formerly everything seemed to be bright, roseate, and optimistic; now there seems to be a determination to calmly and dispassionately try to arrive at an understanding as to what constitutes a cure of epilepsy. Formerly, in many journals, we would see reports headed thus: "A Case of Traumatic Epilepsy of Ten Years' Standing. Trephining; Complete Recovery," or thus: "Trephining for Epilepsy. A Report of Three Cases Cured." Then frequently, after an incomplete or confusing history of the case, in which the fit was not described with any accuracy, you would read that "the patient was trephined over the right Rolandic fissure, and, as nothing abnormal was seen, the wound was closed and the patient went on uninterruptedly to recovery." The next paragraph is probably dated four weeks after the operation and reads: "Patient having had no return of his fits, is discharged cured," the "cured" not infrequently being written with a big C. This is a true portrayal of what apparently, to certain minds, constituted a cure of epilepsy a very few years ago. At the present time the reports read differently. Men seem to be more cautious, more doubtful in claiming cures. They allow more time to elapse between the operation and the report of the case, or they frankly say that not enough time has elapsed since the operation to warrant them in saying how permanent the improvement (if there has been any) will be. The pendulum is swinging the other way, but let us not allow it to swing too far. The experimental physiologist, the clinician, and the surgeon working hand in hand will surely produce results that will lead to a more careful isolation of the operable cases, and thus establish trephining for epilepsy on a more rational and stable basis. The trouble heretofore has been that the cases for operation have not been selected with sufficient care; surgeons have reached too hastily for

[1] Read at a regular meeting of the New York Medico-Surgical Society, January 6, 1896.

the knife and the trephine; they have not reasoned thoroughly and have not discriminated well between those cases to which operation offered a probable relief and those to which it did not. Many poor, old, imbecile epileptics have had holes sawed in their skulls when it was almost as useless to think of stopping their fits as it would be to think of turning back Niagara with a dam of feathers. Again, statistics and reports of cases operated upon have been so frequently misleading because an insufficient time has been allowed to elapse after the operation to justify the opinion as to which were cured and which were not. As a rule these reports have been entirely too optimistic. This brings up the question. What is a cure of epilepsy? This is a very difficult question to answer, and one which, in statistical tables, must be determined arbitrarily. We should not lose sight of the fact that there is frequently a spontaneous remission of the fits; that a change in treatment, even though it be from some of the drugs of known value to a mere placebo, may be followed by a temporary cessation; a mere change of environment will do the same, and any operation, whether it be on the brain or on the buttock, will usually do as much.

The table upon which this article is based is made up of forty-four cases,[1] that I tabulated at the request of my friend Prof. Landon Carter Gray for his article on Epilepsy in "Nervous Diseases by American Authors," to which I have here added twenty-six cases,[2] all having been taken at random from medical journals, making seventy cases in all.

In this table I have regarded as *cured* all cases in which there has been no return of the fits within three years after the operation; *i.e.*, all cases which have been under observation for three years or more after the operation, and in which there has been no return of the fits during that period. With this as a basis I get the following results:

Cured	3
Improved	6
Not improved	14
Death due to operation	3
Improvement; return of fits; malignant brain disease	1
Cases in which there was cessation of fits one year after operation, but in which bromides were used	2
Temporary improvement; time of observation not given	3
Cases in which time of observation after operation was insufficient to make them of value in statistical tables	38
Total	70

[2] See accompanying table.

After a careful tabulation of these cases, and after having invariably given the benefit of the doubt to the reporter, we can only find undoubted cures in three cases (4.3 per cent.), and improvement of more than one year's duration in six cases (8.6 per cent.), while there was unquestionably no improvement in fourteen cases (20 per cent.). Surely this is not a brilliant showing. The percentage of the cured and improved together is only a little more than half as much as the percentage of non-improved. Going still further we find there are thirty-eight cases—54.4 per cent.—in which the time of observation after the operation was not sufficiently long to justify a decided opinion, though a glance at the table will show that extravagant claims were made in not a few cases. It is only fair, however, to say that in these cases there was generally an improvement, sometimes unquestionably so, though usually it was temporary. A question which, to my mind, seems *à propos* is, How much of a probable improvement will justify resorting to so serious an operation as trephining? I know some surgeons will smile and probably throw up their hands in amazement when I speak of trephining as a serious operation, for I have frequently heard the rather flippant remark that trephining under present antiseptic conditions could not be considered dangerous. In answer to this I will only point to my table, where we find three deaths—4.3 per cent.—directly due to the operation; not a small mortality for an operation devoid of danger. The best answer which I can suggest to my question is, Never hastily decide on an operation; take carefully into consideration the patient's environment and his position in life; consider how much his epilepsy interferes with the performance of the duties of life; how far it has been, or probably can be, controlled by drugs; then, if it is an operable case and you think the probable benefits will outweigh the risk involved, operate. When we think how few cases my statistics record when compared with all the cases that have been operated upon, we must easily see how many, many persons have been subjected to this operation when it was useless to expect benefit. It is needless at this time to call your attention specifically to cases of this kind in the table; it does not take a trained eye to detect them. How much better it would have been had these cases not been operated upon! This enormous amount of dangerous work would have been avoided, statistics would have been more accurate, and there would not be so great a preponderance of cases on the wrong side of the

Not given, though suppose convulsions were general.	For two years before operation, as many as 19 daily.	19 years.	.....	Trephine over seat of injury. Dura detached.	Dura firmly adherent, thickened, congested and vascular.	Two slight attacks about 6th day.	.....	1 month.	*Virginia Medical Monthly*, 1894–95, xxi, 942–947.	Time of observation insufficient.
46	J. Allison Hodges.	1864; minnie ball. Depression above and parallel to horizontal line of left squamous suture.	Six months	.....	*Petit mal.* Increasing loss of memory.	As many as 5 or 6 daily.	30 years.	.....	Trephine.	Both tabl's increased in thickness; dura not adherent.	One same night; two more 3 days later.	Slight aphasia and paralysis of one leg about 10th day, but are now passing away. Great improvement in memory.	6 months.	*Ibid.* and *N. Car. Med. Jour.* 1895, xxxv, 33.	Improvement as to memory.
47	J. T. Boutelle.	Five yrs. old; head cut with ax; 16 years old, blow on head from fist. Linear depression, 2 inches long over middle of ant. ¼ of left parietal bone.	"Shortly after" second injury. Increased in severity.	.....	Not given, but suppose they were general.	One to 3 weekly.	2 years.	.....	Trephine. Removal of piece of bone projecting downward to dura.	Piece of bone pressing on dura.	One week.	For six months no fits. Hears they are now "as bad as ever."	6 months.	*Virginia Medical Monthly*, 1894-5, xxi. 813–824.	No improvement.
48	J. T. Boutelle.	Six years old, blow on head; depression of bone.	Ten years.	.....	At first *petit mal*; afterwards severe and "convulsive."	Frequent.	23 years	.....	Trephine. Removal of depressed bone.	Depressed bone; dura slightly adherent.	One week after operation; acute mania due to excitement; fits 2 months	"Now are as bad as ever."	2 months.	*Ibid.*	No improvement.
49	W. Alexander.	1884. "Sunstroke." Injury to left side of head. "Depressed scar."	"Soon after."	.....	General tho' right side, especially right arm more affected. Memory dull.	As many as 7 daily.	4 years.	Oct. 1888	Trephine over depressed scar. Calvarium 3 in. square removed.	"Appeared to have been periostitis, and some erosion of bone, with adhesion of skin to calvarium."	Seven days. Not so frequent as before. Mental condition much improved.	"Distinctly improved. Able to work on a farm."	5 years.	*Brit. Med. Journal*, 1893, ii, 1149–52.	Improvement but Was kept on borax for a long time after operat'n.

No.	Reported by, or Operator.	Date of and Character of Trauma.	Interval between Trauma and Appearance of Fits.	If no Trauma, Age at which first Fit occurred.	Character of Fits.	Interval between and Number of Fits before Operation.	Interval between first Appear'ce of Fits and Date of Operation.	Date of Operation.	Kind of and Location of Operation.	Lesion Found.	Interval bet. Operation and first Fit thereafter. Number of Fits thereafter.	Result as stated by Reporter.	Length of Time under Observation after Operation.	Reference.	Remarks.
50	W. Alexander.	December, 1888. Struck on left side of head between parietal eminence and occipital protuberance.	6 weeks.	.....	General and *petit mal*. Memory and sight failing."	As many as two in one day.	3½ mos.	May 15, 1889.	Trephine. Scar raised from bone	Ridge of bone under line of scar. Dura adherent to ridge, but elsewhere smooth.	Thirteen days. One grand and several *petit mal*.	.....	1 month.	*Brit. Med. Journal*, 1893, ii, 1149-52.	Length of time under observation after operation is insufficient.
51	W. Alexander.	1876; wound of right temple.	Immediately after and for 3 months. Recover'd. No more for nine years when had "epileptic" convulsions.	.....	General. Became stupid.	Two to 15 monthly.	13 years.	1885 & '89.	1885, trephine "without effect." 1889, spicule of bone removed. 1889, dura opened over seat of old trephining, cyst evacuated and drained.	Diffuse cystic condition of dura, inclosing atrophied cerebral convolutions.	Not given.	Improvement at first. Afterward very much worse mentally. In 1893 showed distinct improvement.	3 years.	*Ibid.*	Improven'nt.
52	W. Alexander.	.....	.....	17 years. "Due to exposure to the sun and excitem'nt."	"Looked upon it as one of hystero-epilepsy." Drooping right eyelid, premonitory convulsive movem'ts of right foot.	Not given.	13 years.	Dec., 1891.	Over left motor area. Two one-inch trephine holes 3 inches apart, and intervening bone removed	"Dura seemed healthy," and was not opened.	Occasi'nal headac'es; "Ptosis and newly developed int strabismus of right eye."	"There is no doubt she has benefited by the operation."	27 days, and then "for some time" under care of a colleague in same hospital.	*Ibid.*	Time of observation after operation insufficient.
53	W. Alexander.	December, 1890. Blow on the head. Depressed, curved cicatrix 3 in. long, crossing vertex.	4 weeks.	.....	Visual and gastric aurae, vertigo, general convulsions. Irritable temper.	Two weekly.	12 months.	December 9, 1891.	Trephine. All depressed bone removed.	Thick, dense b'ne press'g on dura, near median line. Dura healthy.	Twenty-four days; Then two more in next fifteen days.	.....	2½ mos.	*Ibid.*	On February 29, 1892, patient reported fits had returned. No improvement.

No.	Reported by, or Operator.	Date of and Character of Trauma.	Interval between Trauma and Appearance of Fits.	If no Trauma, Age at which first Fit occurred.	Character of Fits.	Interval between and Number of Fits before Operation.	Interval between first Appear'ce of Fits and Date of Operation.	Date of Operation.	Kind of and Location of Operation.	Lesion Found.	Interval bet. Operation and First Fit thereafter. Number of Fits thereafter.	Result as stated by Reporter.	Length of Time under Observation after Operation.	Reference.	Remarks.
54	W. Alexander.	.....	.....	Patient 15 years old. Fits since infancy.	*Petit* and *grand mal*. "Congenital and epileptic convulsions." Nystagmus, stammering. Aura in left thumb.	Numerous daily.	15 years.	January 3, 1892.	Trephine over right motor area, 2 1-2 inches by 2 inches, removed.	"Nothing was found exce't considerable amount of fluid."	"During March, '92, the fits left him," and until July, '93, only two attacks of *petit mal*.	"Patient is bright, active, intelligent, and so far operation has been a success."	18 months.	*Brit. Med. Journal*, 1893, ii, 1149-1152.	Improvem'nt
55	W. Alexander.	Depressed fracture, upper extremity of parietal and adjacent occipital bone, right side. Injury not recent.	Not given.	.....	"Attacks mixed. Began mostly on right side."	Not given.	Not given.	Nov. 29, 1892.	Trephine. Cyst drained.	Calvarium imperfect at one spot; atrophied convolutions and enlarged veins.		"Fits much less frequent and mother says are lighter."	Reporter saw patient last on Oct. 21, 1893.	*Ibid.*	History insufficient. Observation insufficient.
56	W. Alexander.	"Bump on top of head," middle of left parietal bone; 2 in. below median line, forward to left frontal bone.	.....	No history of trauma.	*Petit* and *grand mal*, mostly the former; goes down on knees, unconscious. In a moment get up confused, laugh and go on at play.	Numerous daily.	"Many years."	June 15, 1892.	Trephine. Removal of one sq. inch and a half of thickened bone.	Fibrous layer, 1 1-2 in thick, covering the bone. Bone 1 1-2 in. thick, and dura thicken'd.	"Attacks diminish'g month by month; usually 1 daily, but several days have passed without any."	I look upon this case as very hopeful.	16 months.	*Ibid.*	Report seems to show slight improvement. I think reporter takes too roseate a view.
57	W. Alexander.	1888. Scar over right motor area.	"Soon after."	.....	Left side of face and left hand. Headaches.	Numerous	5 years.	Febru'y 2, 1893.	Trephine over right motor area.	"Some excess of fluid was found; otherwise normal."	Not given. July 29, '93, "quite bright and intellige't, in contrast to previo's depressed state."	"Headaches disappeared, fits much less frequent." "Oct. 21, '93, still improving."	8 1/2 mos.	*Ibid.*	History not complete. Subsequent observation insufficient. Reporter takes too roseate a view.
58	W. Alexander.	.....	.....	"Congenital imbecile epileptic," 11 years old.	"At first were one-sided."	Not given.	11 years.	March 2, 1893.	Trephine. Removal of depressed bones, 2x2 ins., over left motor area.	Depressed bone. "Excess of clear fluid beneath dura." Convoluti's looked healthy."	.....	July 29, '93—Child is much improved, learning to spell, and has had fewer attacks since operation.	1 1/2 mos.	.....	History is not complete. Time of observation insufficient.

No.	Reported by, or Operator.	Date of and Character of Trauma.	Interval between Trauma and Appearance of Fits.	If no Trauma, Age at which first Fit occurred.	Character of Fits.	Interval between and Number of Fits before Operation.	Interval between first Appear'ce of Fits and Date of Operation.	Date of Operation.	Kind of and Location of Operation	Lesion Found.	Interval bet. Operation and First Fit thereafter. Number of Fits thereafter.	Result as stated by Reporter.	Length of Time under Observation after Operation.	Reference.	Remarks.
59	J. T. Eskridge.	1866. Blow on left side of head.	10 years. Second fit one year after.	.....	Numbness and tingling right thumb and fingers, hand, and throughout right side. Convulsive movem'ts then became general.	Daily for 3 or 4 years before.	18 years.	March 30, 1894.	Trephine over middle one-third of Rolandic fissure. Cortex 1 in. in diam. by 1/2 inch thick, including centr's for th'mb and index fing'r excised.	Bone thickened, but no fracture, or adhes'n of dura.	Seventeen days. Fit produced by rubbing cicatrix of wound. Another fit next day.	Marked improvement in appearance and mental condition. Paralysis right hand and arm, and lower part right side of face.	2 1/2 mos.	Tr. Col. Med. Soc., 1894, 343-358.	Time of observation after operation insufficient. Evidently no improvement as to fits.
60	J. T. Eskridge.	April, 1890. Fracture of right parietal bone and depression.	7 months. Second fit 12 days after.	.....	Specks before eyes, unconsciousness, falls; contraction of left hand, and left foot jerks. Then become general.	One or two weekly.	10 months.	Sept'ber 6, 1891.	Trephine over seat of injury and removal of depressed bones.	Depressed bone, 2 in. long, and 3-4 in. in width.	One week; 2d, one month; then one every two or three months; there was a cessat'n for 6 mos. in '93 and '94.	Greatly relieved. Mental condition much improved.	2 yrs. and 9 months.	*Ibid.*	Improvem'nt.
61	J. T. Eskridge.	.....	.....	When two days of age had spasms for 2 days.	"When 3 yrs. old developed epilepitc attacks. . . . Would fall on right side of face."	From 1 in two weeks to 2 or 3 daily.	Nearly 4 years.	October 9, 1891. 1893.	Lin'r Craniect'y on right side. Some mos. afterw'rds the same on left. A strip of bone 1/2 in. by 2 over left Rolandic fissure removed.	.....	Lessened fits for a year after first operations, then recur'd with considerable frequency.	Convulsions ceased for some time, but have since recurred. Mental improvement.	About two years.	*Ibid.*	This was an idiotic child, evidently of the porencephalic class
62	Walker.	1874. Struck on head with scissors.	19 years. First fit followed by physical and mental excitem't.	.....	Begin on right side, and become general.	Two to five daily.	About one year.	1894.	Trephine: Evacuati'n of cyst. Spicule of bone removed.	Cicatrix 1 in. long, above left parietal eminence. Fissure in bone, cyst admitting ind. finger spicule of bone.	Not given.	Doubtful.	4 weeks.	Cincinnati *Lancet Clinic*, 1894, N. S., xxxii, 174.	Time of observation after operation insufficient.

No.	Reported by, or Operator.	Date of and Character of Trauma.	Interval between Trauma and Appearance of Fits.	If no Trauma, Age at which first Fit occurred.	Character of Fits.	Interval between and Number of Fits before Operation.	Interval between first Appearance of Fits and Date of Operation.	Date of Operation.	Kind of and Location of Operation.	Lesion Found.	Interval bet. Operation and First Fit thereafter. Number of Fits thereafter.	Result as Stated by Reporter.	Length of Time under Observation after Operation.	Reference.	Remarks.
63	Wood and Cotterell.	1891. Fell from hay-rick. No apparent injury at the time.	Ih a few weeks had what appeared to be epileptic fits.	.....	Always began in right thumb and finger; became unconscious. Paralysis of right arm and leg.	.....	About 2½ years.	Febry 2, 1894.	Trephine over mid-dle of left Rolandic fissure. Cyst drained.	Serous cyst under thickened, and adherent over cyst.	Not given.	March 17, '94. Walks without support; had opened sponta-neously. No fits since operation. Left hemiplegia remains	6 weeks.	*Brit. Med. Journal*, 1894, i, 10.	Hemiplegia withepilepsy. Improvement. Time of observation not sufficient to justify prognosis.
64	Carline.	1888. Injury by scar to head from fall of iron girder and rubbish. Unconscious one week.	3 years; followed excessive physical fatigue.	.....	Spasm of left face, both eyes to left, and then body became flexed to left. Forgetful; violent temper.	Four to five daily.	5 years.	July 4, 1893.	Trephine. Two discs of bone 1 inch in diameter removed from over right motor area. Dura not opened.	Ridge of bone, 1½ ins. by ½ in., back-ward from centre for elevator in angle of mouth. Periosteum dipped into adherent bone. Smooth growth of bone trimmed flat. Dura rough, adherent over lower extremity of ascending convolution.	One slight fit next day, but none subsequently.	Cessation of fits although could not have been more than six months, as case was published July 7, '94.	Not given.	*Brit. Med. Journal*, 1894, i, 98.	Patient became childish, mischievous, very forgetful, and violent temper" after accident. On a journey lost his way and had to tramp 75 miles. Time of observation after operation is short.
65	R. H. Cunningham.	1892. Struck with a brick 6 days after injury. Comparatively slight injury on left side of head anteriorly.	Numerous. Complete paralysis of right side and of speech. Operation 6 days after injury. More or less complete recovery of power and speech, though fits still occur.	.....	Numbness and tingling, right hand. Thumb turns in; convulsions of arm, shoulder, and face; head and eyes to right; speech lost; consciousness retained.	Two weeks.	About two years.	January 20, 1894.	Trephine and tem-porary Paraspeni-cal over Rolandic. Adhesions broken up and part of dura removed.	Large, adherent cicatrix, 1 in. behind and 3½ ins. above left ext. ang. proc. Dura thickened, and membrane adherent over post. central, pre-central, post. tip of 2d frontal, centre of old cicatrix, & over lower extremity of ant. central.	Not given.	Cessation of fits although could not have been more than six months, as case was published July 7, '94.	Not given.	*N. Y. Med. Journal*, 1894, ii, 15.	Improvement. Time of observation after operation is short.

66	Ellingwood and Fischer.	1882. Injury to left frontal region. Fever and almost constant headache for 2 1-2 months.	4 months.	.....	Sense of weakness in right side; right hand cramped, arm raised, wrist flexed and rotated inward to extreme limit, head to left.	About nine yearly.	10 years.	July 1, 1892.	Trephine over hand centre, left side; dura opened. Aug. 26th abscess at side op'ration; curetted and drained.	"Nothing abnormal found."	First fit same day, and six more in a mo'h. After second operation fits ceased for two months.	.....	5 months.	*Pacific Medical Journal*, '93, xxxvi, 65–70.	No improvement.
67	Geo. W. Cole.	Blow over Rolandic fissure when 9 years old.	3 years.	.....	Hands first, feet and lower extremities. General convulsions.	At intervals.	2 years.	Not given.	Mallet and chisel. Bone large as 5c piece removed from over upper end left Rolandic fissure.	.....	.....	Too soon to report case, but he is inclined to believe relief will be permanent.	.....	*St. Louis Clinique*, 1892, v, 44. Abstract of rep'rt to St. Louis Med. Soc.	Time of observation after operation insufficient. Cannot see what he bases his belief on.
68	J. I. Darby.	When 1 years old struck by sharp stick on left side of head.	About 12 yrs. old.	.....	General, but right side affected more than left; mind becoming affected.	Occasional fits for 3 years, but had been getting worse lately.	3 years.	Not given.	Trephine. One-half inch button over most depressed portion removed. Dural adhesions brok'n up.	Depressed cicatrix over middle of left parietal bone; dural adhesions.	.....	For several months frequently felt aura, and had giddy sensations, but they disappeared entirely, and to date no fits. Mind also cleared up.	6 to 7 yrs.	*Alabama Medical and Surg. Age*, Anniston, 1891–'92, iv, 113–116.	Cure.
69	W. B. Rawson	1885. Knocked down and rendered unconscious.	One day.	.....	Tingling left thumb; spasm of left thumb, arm, shoulder, face; consciousness usually lost. 1886—Probably meningitis, after which visual aura. 1891—Impairment of motion, and sensation in left hand; smell lost; nearly blind.	Increased in number.	Six years.	April, 1891.	Trephine 2½ inches d'wn right Rolandic line. Thickened dura cut aw'y, bone discs replaced. Mch., 1892, sec'nd operation. Bone discs and adhesions removed.	Cystic accumulati'n of fluid 1 in. in diameter between pia and thickened dura.	Fewer fits after first operation, but they soon came back. H'd-aches.	April, '93—No pain, being few and slight fits.	About one month after second operation.	*Brain*, '92, xv, 437–442.	Faradization over the site of trephining. Improved motion and sensation. Apparent improvement in fits. Time of observation too short.
70	R. Parker and F. Gotch.	October, 1891. Injury to right side of head.	3 weeks.	.....	Tremor and twitching of left hand, forearm, head, eyes turned to right. Only mom'tary unconsciousness, but in June, 1892, was first kno'n to fall.	Twenty to 30 daily.	One year.	Dec., 1892.	Trephine over right Rolandic fis'e, 1x1½ ins. bone removed, thumb & wrist centres isolated and excised.	Apparen'y none; not stated.	Nine fits the same day.	March 6, '93—Had reported 4 to 10 fits daily. "Since then improvement has taken place."	5½ mos.	*Brit. Med. Journal*, 1893, i, 1101-1103.	Horsely had suggested an excision of the shoulder area. Time of observation too short,

column. As I have said before, the percentage of cured and improved is not great. It is not so small, however, that we should feel discouraged, and we should not for one moment think of abandoning the operation. Let it rather stimulate us to greater zeal in the selection of our cases, to train our minds to a nicer discrimination between the operable and the non-operable; and we will find much more glory will be brought to our profession, much more confidence begotten in the minds of the laity, just as much suffering relieved, and fewer lives jeopardized. In these matters the skill and judgment of the physician will, of course, be the most powerful factors, but there are certain broad principles which should always be borne in mind:

(1) Always consider an epileptic fit as a symptom of some underlying condition. (2) Inquire particularly and very carefully about the first convulsion: What was its apparent exciting cause; what was its character, general or affecting only certain portions of the body, and what portion of the body was affected at the beginning of the fit? (3) If there was an aura, investigate it carefully, as it will not infrequently give a clue as to the seat of the lesion. (4) If there has been a trauma or a suspicion of trauma, shave the head and look carefully for a scar or a depression. If there is evidence of a trauma in a position corresponding to the initial symptoms of the fit, an operation is usually justifiable. (5) If you cannot get a clear history of the case, give a placebo and place the patient under competent surveillance until you can satisfy yourself as to the character of the fits. (6) Do not operate on a porencephalic child and expect to cure the epilepsy. Do not, as a rule, operate on a case of post-hemiplegic epilepsy in a child and expect to cure. (7) Do not operate on an old, idiotic epileptic, a victim of idiopathic epilepsy, with general convulsions of years' standing.

What, then, is the value of operative interference in the treatment of epilepsy? In the light of our present experience, I think it will be fair to put it thus:

a. A certain small percentage of the cases will be cured.

b. A certain larger percentage will be improved.

c. An even larger percentage still will not be improved at all.

d. An operation upon almost any case will produce a temporary cessation of fits.

Dr. Otto H. Schultze has been appointed coroner's physician of New York city to succeed Dr. Huber, who recently resigned.

CLINICAL LECTURE.

RACHITIS AND MALNUTRITION.—CARCINOMA OF LIP AND JAW.—FRACTURE OF BASE OF SKULL.

(Delivered at the Buffalo General Hospital.)

By ROSWELL PARK, A.M., M.D.,
of Buffalo, N. Y.;
Professor of Surgery, University of Buffalo.

Case 1.—This child, aged five years, is the youngest of five children of a family in very poor circumstances. He has been brought to the clinic to have us ascertain why he has never been able to walk, and to relieve him if possible. This case is not typical of any one lesion, yet we can readily make out that rachitis exists, and perhaps it will be more instructive to show you an atypical case than one which you could scarcely fail to diagnose properly.

As I hold the child in a standing position, you will observe the aldermanic protrusion of the abdomen; but this is not due to fat, for the child is not very well nourished. The liver is large and prominent, and the flabby abdominal wall allows the distended stomach and intestine to project beyond the meagre outlines of the rest of the trunk. Although the child has instinctively contracted the abdominal muscles so as to oppose my efforts at palpation, I can still feel the spleen to be somewhat enlarged. The shape of the head is not very characteristic, though the squareness of the occiput and the prominence of the occipital and parietal bones are readily distinguished. In spite of his age, the anterior fontanel has not yet closed. In examining for it, I find corroborative evidence of the neglect which often leads to rachitis in the presence of parasites. The lower part of the face is not deficient as it is in typical cases of rickets, and the teeth are now in a nearly normal state, though their appearance was very likely delayed; of this we can obtain no reliable information. The chest shows one of the mechanical signs of the disease in the flaring out of the lower ribs. Below the thorax you notice a transverse groove, which is more marked in inspiration, on account of the laryngeal obstruction which usually complicates this disease to a greater or less degree. I can feel the relics of protuberances at the junction of the ribs with their cartilages. The same condition in a higher degree is known as the rachitic rosary. The arms and legs are shrunken and the legs notably deficient in development, considering the age of the child. The bulging at the epiphyseal lines and the bowing of the tibiæ and femora are not well marked here, doubtless because there has not been the ability to walk and thus subject the growing bones to the weight of the body before they were in condition to support it.

Rachitis is essentially a disease of nutrition. We do not see in Buffalo the number of severe cases that present themselves in larger, and particularly in more crowded, cities, for we must remember that our city, though twelfth in order of population in the United States, enjoys many of the hygienic advantages of towns of ten thousand inhabitants. Although mild grades of rickets are common, even when we can assign no definite hygienic reason

for it, typical cases are relatively rare in the United States. On the other hand, 80 per cent. of the children who are brought to the dispensaries in London and Vienna are rickety. Not to mention the scientific etiology of rachitis, we may say that its cause is neglect — the neglect of ignorance and carelessness, or the forced neglect of poverty. Hence, other things being equal, we find the most marked and most frequent illustrations of rickets coincident with the grossest ignorance and the deepest poverty. The symptoms of the disease usually manifest themselves at the period of first dentition. As to treatment, the first indication in such a case as this is to make the child clean and comfortable and to supply it with nourishing food in proper quantities and at proper times. Of the tonic treatment designed especially to stimulate the development of bone I do not care to speak at present, as you are undoubtedly familiar with it from your medical lectures.

Case II.—Our first operative case is a pitiable example of neglect. The patient, a man of 45, had a cancer removed from the lower lip three years ago. Whether the operation was thoroughly done or not, we have now no means of ascertaining. Some time after the operation, however, he noticed a mass involving the lower jaw, which has been allowed to grow till his condition is now very serious. He has also some facial paralysis on the side of the tumor. Such paralysis may be due to atrophic changes produced by pressure on the seventh nerve in a variety of ways; but in a case of this sort we would naturally ascribe it to the presence of the cancer, though the possibility of inflammatory trouble in the passage through the temporal bone, or of other lesion which might occur in a person not the subject of malignant disease, must not be forgotten. I presume, however, that the paralysis is due to the pressure of the cancerous mass at some point after the nerve has emerged from its foramen. I have told the patient that the operation may not be ultimately successful, and that he may even die as the immediate consequence of an attempt to remove the mass, and that any operation which could be seriously considered as affording him a chance for relief will involve the sacrifice of half the jaw-bone. Notwithstanding that I have given him no encouragement as to the result of the operation, he has not been deterred, and has almost insisted on my giving him whatever chance surgery can afford.

Case III. This patient was struck yesterday by a Belt-line train. He suffered severe contusions about the head and he has been bleeding from the ears and nose, so that the question has arisen as to whether there is a fracture of the base of the skull. If there is a depression of the outer table, we shall know where to look for a possible depression of the inner table also, yet we must bear in mind that one table may be broken without a corresponding lesion of the other. If the inner table be broken, a meningitis may develop on account of the irritation caused by the pulsation of the brain against the sharp edge of the broken bone; again, if an acute meningitis is not thus caused, a localized chronic form may develop, with thickening of the membranes and sclerosis of the cortex in immediate contact, and then we have all the conditions favorable to the development of epilepsy later on. Thus it is at present considered good surgery to make an exploratory trephining in any such case, to remove the depressed fragments or restore them to their proper level, and then allow the case to go on to a perfect recovery—perfect at least so far as the result of the operation is concerned, for aseptic interference need produce no trouble nor add to the gravity of the case.

The one great lesson to be learned from cases of this sort is not to trust too much to nature. We must also be cautious about giving too favorable a prognosis and about judging the condition of the inner table from external appearances. I can recall three or four cases in which the outer table was absolutely intact, except for a slight fissure, when there was no loss of consciousness, and yet the result of operative interference showed that the inner table was depressed and amply justified the exploratory trephining. If these cases had been left to nature, either acute meningitis would have developed (when the patient would almost certainly have died) or else the later fibrous changes would have led to epilepsy.

Once in a while it is better to leave the patient to the chance of a spontaneous recovery, rather than to operate without proper preparation. It does not require much attention to aseptic details, however, when it is only necessary to go through the skull without penetrating the dura. Often we have had patients brought to the Fitch Hospital with penetrating wounds of the skull filled with cinders and dirt, and we have cleaned out the foreign matter, sewed the wound without drainage, and had union in thirty-six hours. We could not expect such a result in other parts of the body, but the vascularity of the scalp is such that phagocytosis is at its greatest activity, and so, too, is the reparative power of the cells. It is necessary, however, to remove the foreign matter absolutely and render the field of operation thoroughly aseptic in order to have union by first intention. Still, if you are so situated that perfect asepsis is impossible, the patient will, in all probability, recover if the brain is not exposed.

You will notice swelling and redness about the eye. This is due to the extravasation of blood into the large amount of loose cellular tissue that surrounds these parts. The wound is a curvilinear tear over the right anterior parietal region. I will enlarge the wound, carrying the incision in a horse-shoe shape. I am now down upon the fracture, which is simply a fissure in the bone, into which I can merely drive the flat end of a probe. We cannot tell how large the fracture may be in the internal table. With the chisel I detach a long sliver of bone, starting just above the orbit and running parallel to the fracture. Now, under the force of the mallet striking the chisel, fifteen or twenty cubic centimetres of clotted blood and grumous material well up from beneath the bone, having been lodged either beween the skull and the dura or between the dura and the pia.

The appearance, now that I have penetrated the bone, shows the wisdom of interference. The innocent-looking fissure has led down to a wound in the brain tissue, from which there is still considerable oozing of blood. I am trying to stop the hemorrhage by stuffing gauze into the

wound. Now, after biting off the margins of the bony opening with the rongeur, I have exposed the smooth, shining surface of the dura, from which the brain protrudes in a mass as large as a hickory-nut. The pulsation can be plainly seen in the protruding cerebral tissue, but not in the dura. Most of the hemorrhage comes from a vein in the dura, and this I will ligate with fine catgut.

The suspicion of fracture in the middle fossa of the skull, on account of hemorrhage from the ear, renders the prognosis much more guarded than it otherwise would be. There is some dilatation of the pupil on the right side that makes me suspicious of a clot on the opposite side of the brain. Still, in the absence of paralysis, I do not feel justified in trephining on the other side. We shall therefore await developments. The pulsation in the brain is beginning to be more free; it is slow, corresponding with the pulse—40 to 50.

There is some hemorrhage from the margins of the bone, which I shut off by pinching the bone together with forceps. Some little bleeding points that remain I close by pressure with a sharp-pointed probe.

In a case like this, when it is certain that there will be some inflammatory exudate, it is a great mistake to tightly sew up the dura. By so doing you increase the pressure on the brain and to that extent defeat your object in operating. As the exudate organizes, the wound in the dura will unite. Neither do I believe that there is any necessity in cutting off the protruding mass of brain tissue. I shall simply tuck in gauze so as to cover the dural wound and then dress the remainder of the wound in an antiseptic manner, uniting the scalp in part, but leaving room for drainage.

I have seen two or three cases of undoubted basal fracture which recovered without operation, and in which, from the pressure signs, there must have been some hemorrhage. Laplace, of Philadelphia, has recently operated on such a case, churning up the clot and evacuating it; but it may be questionable whether the case would not have recovered without operation, and, thus far, we have very little precedent in regard to operations on the base of the skull. It does not seem to me that the pupil is as much dilated as when I began the operation, and this I take to be an indication that the pressure has been relieved.

CLINICAL MEMORANDA.

A TRUANT URETER.

By W. H. MAXSON, M.D.,
ST. HELENA, CAL.

I REPORT the following case as one of unusual interest, from the fact that such abnormalities are rarely met with. Three cases so far have been reported, two of which only came to operation. The first of the kind was published in the New York *Medical Journal*, December number, 1878, by Dr. W. H. Baker, and operated upon with success. A second case was reported in the *British Medical Journal* of December 6, 1884, by Dr. Thomas More Madden, of Dublin, Ireland. This case, however, did not come to operation. The third case was reported in *American Gynecological Transactions*, Vol. 15, 1890, by Dr. F. H. Davenport, of Boston. This case came to operation on February 11, 1890, and the first operation not being wholly satisfactory, the case was again operated upon March 11, 1890, with success. Three cases, including my own, have now been operated upon successfully, and it is to be hoped that others who may be suffering in the same manner may be induced to submit to the same treatment for relief.

Miss H., age 22, healthy, robust, never subject to any other than children's diseases; family history above suspicion. She had suffered from what she supposed was simply incontinence of urine, as she says, as long as she could remember, being obliged to wear a napkin continually night and day, and at the same time voiding at regular intervals urine, as she supposed naturally. Her condition gave her no end of trouble and inconvenience, and most of the time she felt that she was ostracized from society. She had consulted physicians, but all to no purpose, and had been obliged to bear this great misfortune —for such it was—all her life. Having heard of some cases that were benefited, she took new courage and applied to me for treatment January, 1893, in the hope that she might be relieved of the incontinence of urine. After an examination, it was found that she presented, as far as we could see, natural organs, and no indications of disease. Her urine was examined and found to be negative; and as there were no outside indications of the cause being other than simple incontinence, she was placed under treatment for the space of a month. The capacity of the bladder was measured and found normal; urine examined with negative results. Electricity, both faradic and galvanic, was used in appropriate strength, with a view to stimulating the sphincters to their proper tension. At the end of a month no perceptible change could be noticed, and the case looked discouraging.

Thinking that it was useless to continue treatment further in that line, we recommended a forcible dilatation of the uterus to relieve dysmenorrhea, with which she suffered expecting that to end our connection with the case. While under an anesthetic, however, we took occasion to make a more critical examination of the urethra, and then learned the cause of the incontinence. By the use of probes we could clearly demonstrate that the left ureter, instead of opening into the bladder, opened on the outside of the body, in common, however, with the external meatus of the urethra, but outside the external sphincter, as demonstrated by passing one probe into the bladder and another into the ureter; and by dilating the external meatus slightly we could distinguish the bridge separating the urethra and ureter, about one-fourth of an inch from the external surface. With the probe the left ureter could be traced up the vagina its entire length, and lying just beneath the mucous membrane.

After a careful consideration of the anatomical relations present, I recommended a radical operation for the relief of the patient, consisting of dissecting the ureter up to the walls of the vagina, and at a convenient place turning it into the bladder. I had never seen or heard of a case of the kind, and consequently asked counsel, taking

the case before four of the most distinguished surgeons of San Francisco—Drs. Lane, Plummer, Gibbons, and Cushing—who corroborated fully my diagnosis.

Thus encouraged, on the 26th of February, 1893, the young lady, after a careful preparation, was put under an anesthetic. Several surgeons assisting, I made the incision through the vaginal wall from the external meatus of the urethra up the vaginal wall about four inches over the line of the truant ureter, dissecting off the mucous membrane from the ureter that distance. I then passed a slender, long pair of dressing forceps, slightly curved, into the ureter, spreading the blades sufficiently to keep the ureter on the stretch, in order to prevent incising it while dissecting it out, which I succeeded in doing without any injury whatever to it. At the distance of about three and a half inches I reached a point where the base of the bladder came into close contact with the ureter. I then passed a curved sound through the urethra into the bladder, adjusting it in the base of the bladder at the point where the contact with the urethra was to be made, at which place I made a sufficiently large opening through the bladder. Finding that the ureter, dissected up, was much longer than necessary, I cut off about an inch and a half. I then put in a long suture in the end of the ureter, and looping the end of it over the sound, drew the sound back through the bladder and urethra, drawing with it the suture which was to pull the ureter through the opening in the bladder to the extent of an inch at least. I then stitched the ureter into the walls of the bladder, using catgut sutures, and the vaginal wall was closed over the former site of the ureter. I then passed into the bladder a gum elastic catheter and attached the ligature on the end of the ureter to the catheter, in order that the suture might hold the catheter *in situ* and that the catheter might make a continual mild strain on the ureter. The case was then put to bed, and made an uneventful recovery, with the exception of a stitch abscess, which discharged per vaginam, and a slight cystitis, caused by the irritation of the catheter. The catheter drained the bladder continually for two weeks. At the end of the second week the suture came away. The third week the urine was drawn every three hours, at the end of which time the patient was given free use of the bladder, with the instruction to void the urine quite often, as indeed she was inclined to do from a slight irritation. She was kept quiet for two weeks longer, after which time she has had normal use of the bladder, the urine passing normally.

It is now over two years since the operation. I have heard from the case occasionally, and have had the pleasure of making an examination twice. From all appearances I could not hesitate to pronounce the operation a success. It is needless to say that the patient was overjoyed as time proved her free from the distressing symptoms of incontinence.

The sixty-third annual session of the Medical Society of the State of Tennessee will be held at Chattanooga on April 14th, 15th, and 16th next. An interesting program, containing 38 papers, has been prepared.

TWO CASES OF ABSCESS IN THE MASTOID REGION, ASSOCIATED WITH DIABETES MELLITUS.

By R. A. URQUHART, M.D.,
of Baltimore, Md.

While the occurrence of boils and carbuncles on various parts of the body surface has long been recognized as a feature of diabetes mellitus, recent agitation of the question tends to show the mastoid process especially prone to be a seat of inflammatory change in this disease.

Just why this region proves to be a point of least resistance is difficult to explain. The cells and cavities of the middle ear being anatomically almost one and the same leaves no room for surprise at involvement of the cells after the establishment of otitis media—but why it should arise in the diabetic diathesis is by no means so evident.

The cases reported below are from a limited number treated in St. Agnes Hospital, Baltimore:

Case I.—Mrs. D., aged 57 years; admitted June 6, 1895, in fairly good condition; gives history of probable diabetes for the past six or seven years; passing about eighty ounces of urine daily, which showed 3 per cent. sugar; has inordinate appetite and thirst, and numbness and tingling of peripheral neuritis. Some days after admission several boils developed on various parts of the body surface and face, followed by complaints of pain in the region of the right ear. Careful examination showed only some slight redness of the drumhead, with a slightly reddened and swollen condition of the external auditory canal, most marked along the posterior wall.

The condition rapidly grew worse, and examination on the following day showed an auditory canal quite swollen and red, with marked congestion and bulging of the membrane, with some little exudation of pus from a previously existing small perforation in the lower posterior portion, with an exquisite tenderness to pressure over the anterior region of the process where there had developed no marked signs of inflammation. There were severe neuralgic pains over the right side of the face, with tinnitus and giddiness, the temperature at no time registering more than 101°.

The treatment consisted of constant hot-water application, with frequent irrigations with saturated solution of boric acid, drainage being effected by way of the middle chamber through the perforated membrane. The tenderness slowly left the region as the suppurative exudation decreased, and was followed by no serious involvement of the organ.

Case II.—Patient, Miss N., aged 65 years; admitted September 15th; poorly nourished; family history negative; urine passed in moderately large quantities, examination showing a small per cent. of sugar with phosphates largely increased, suggestive of the so-called phosphatic diabetes. The constant presence of sugar on repeated examination, however, showed a disordered nutrition, unquestionably of diabetic origin.

In this case, at no time has there been a tendency to furunculosis other than in two instances, in each of which the ear has been the region involved. In the first, the boil developed in the external auditory canal posteriorly; was of small moment and short duration, yielding readily to

early evacuation with subsequent irrigations, the membrane being in no manner involved, nor did the mastoid region appear affected.

In the second instance the mastoid region has been alone involved—the inflammatory process developing slowly but steadily—responding with slight pain only, at first, to deep pressure, with increasing swelling and redness, the upper anterior region being probably most noticeably tender. The tympanic membrane, at first unchanged, never showed more than mild congestion, while the external auditory canal in its posterior wall alone was affected—where there was no well marked inflammatory condition. Hearing at all times was acute; the temperature reached 101°. There were acute neuralgic pains radiating over the side of the face and head, but no other symptoms referable to other parts.

Deep incision over the affected area showed a diseased periosteum with unhealthy appearance of the bone below but no carious particles were noted; however, the length of time that a free discharge of pus took place suggests more than a periostitis. If this is a case of inflammation of the cells, apparently we have a primary involvement of the mastoid region in no manner traceable to a disordered condition of the tympanic cavity, for at no time has its involvement been of serious moment.

In neither case was the otitis media, if indeed this condition could have been present in the latter, traceable to inflammation of neighboring structures, pharynx, or Eustachian canal. That there does seem especial tendency to inflammatory changes in the mastoid region in the dyscrasia under discussion, there is unquestionable evidence, but as to the existing relationship we are as much in the dark as we are ignorant of the true nature of the diabetic diathesis.

NEW APPARATUS.

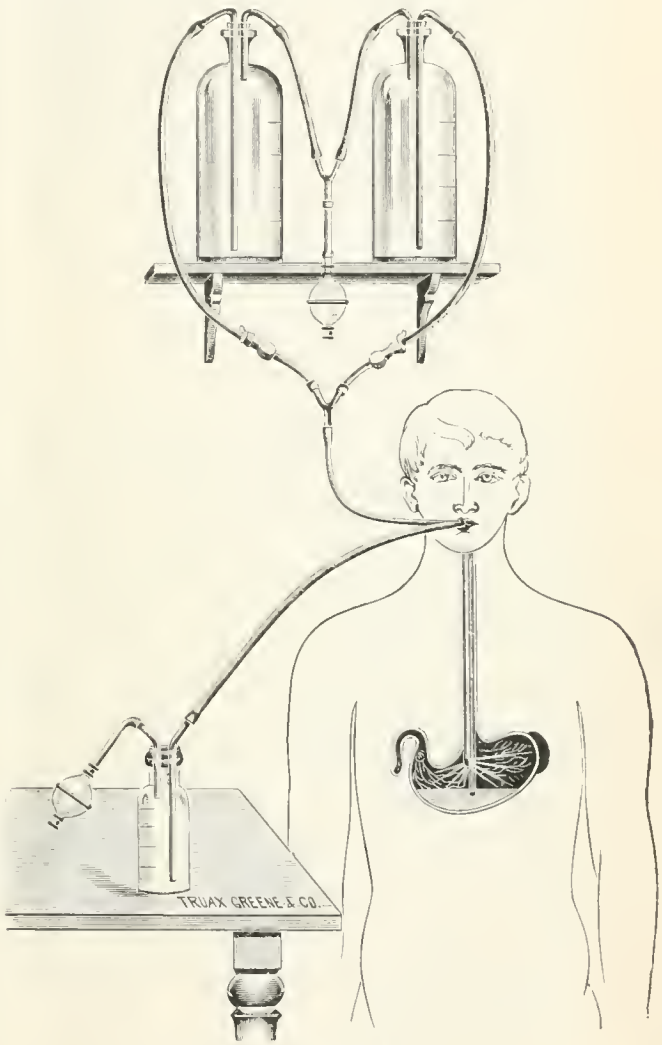
A PNEUMATIC FORCE IRRIGATOR FOR ALTERNATING HOT AND COLD WATER, AS USED WITH TURCK'S STOMACH NEEDLE-DOUCHE.

By FENTON B. TURCK, M.D.,
OF CHICAGO.

THIS consists of two large bottles, A and B, with closely fitted corks, pierced by two glass tubes, one of which reaches to the bottom inside of the bottle, like a siphon. To each of these glass tubes is attached a rubber tube of suitable length. Each rubber tube is supplied with a shut-off clasp, which may be easily opened and closed. A Y-shaped glass tube connects the two extremities of the rubber tubes. To the remaining, or stem, end of the Y-shaped glass tube, which is in connection with the long tube inside the bottle, is attached a rubber tube of any desired length. To this tube may be attached the double stomach-tube (needle-douche) or any point or tip used with the irrigator.

To the remaining, or stem, end of the second Y-shaped glass tube a rubber bulb (or any apparatus for the compression of air) is attached by means of a short rubber tube.

In order to fill the bottles, connect the long tube with the hot or cold water from the hydrant; in absence of hydrant use the water from an elevated vessel. After the bottles have been half filled, they are ready for use. In order to increase the force of the stream, all that is necessary is to pump in air, compressing it upon the body of water. The stimulation of the rapidly alternating hot and cold water, together with the impact of the small needle-



PNEUMATIC FORCE IRRIGATION.

like streams of very greatly increased force, acts as an intense vaso-motor and cellular stimulant. The cleansing power is also enhanced by the increased force of the stream; it is used also for a general irrigator. Besides cold and hot water, different solutions can be kept in bottles on hand ready for immediate use.

No. 1 THE PLAZA.

A RAPID METHOD OF FILTERING.

By SAMUEL H. FRIEND, M.D.,
MILWAUKEE, WIS.

SINK a tightly fitting pledget of absorbent cotton about one inch (2.5 ctm.) from mouth of test tube; fill the space

above with urine or fluid to be filtered. Place the opposite end of tube in running hot water, or water ranging between 120° and 150° F. (50 to 60 C.), or heat tube with a gas or alcohol flame. The result will be that the heated air in the tube will rise—following the law of the expansion of gases—which is manifested by the appearance of bubbles on top of the fluid layer. As soon as this is observed submerge the bottom or heated portion of the tube into water ranging between 40° and 70° F. (5° to 20° C.). The result is manifested immediately by the disappearance of the layer of fluid from the top, and its appearance in the bottom of the tube. This process may be continued indefinitely until the necessary quantity of urine or fluid is collected. The latter action is the result of suction, produced by the elasticity of the atmosphere and its pressure in refilling the partial vacuum.

This method is especially useful in the chemical examination of urine containing pus, and could also be used in making a rough estimate of solids held in suspension.

MEDICAL PROGRESS.

Epidemic Stomatitis.—At a meeting of the Laryngological Society of Berlin, SIEGEL (*Revue de Laryng., d'Otol., et de Rhinol.*, 1895, No. 24, p. 1184) stated that this disease presented itself generally in the form of an affection of the whole alimentary canal from the mouth to the anus; the descending portion of the large intestine is affected with particular frequency. The liver and kidneys often show alterations, and sometimes an exanthema occurs, in appearance somewhat between measles and scarlatina. In the mouth considerable inflammation and edematous swelling is observed, especially in the uvula, the faucial pillars, and the gums, and the latter present also scorbutiform lesions; the tongue is often much swollen; the formation of bullæ in the mouth, the pharynx, and the epiglottis is not rare, the gums are often retracted, the lingual mucosa in a state of desquamation.

In about thirty sections the author found a specific bacterium, and once a short bacillus showing a clear point in its center. He showed a preparation from the kidneys, in which a colony of specific micro-organisms was seen in a glomerulus.

E. MEYER presented two patients in whose feces SIEGEL found specific bacilli.

Phleginonous Lingual Amygdalitis (*lingual angina*, of DAVID CAIGIE; *basic glossitis*, of A. BROCA).—E. ESCAT, (*Revue de Laryng., d'Otol., et de Rhinol.*, 1896, No. 5, p. 129) reports the case of a shoemaker, 33 years old, who, being nearly cured of an angina, which had been cared for at home for eight days, experienced on the ninth day a relapse. The febrile symptoms—insomnia, cephalalgia, burning thirst—soon reappeared in a far greater degree than in the first attack. The patient complained of difficulty in deglutition, even of liquids, left otalgia, and the sensation of a foreign body in the throat. The mucosa of the buccal pharynx was the seat of a moderate diffuse catarrh; the faucial tonsils were slightly swollen, but otherwise negative, some edema of the subhyoidian region, and the inmobility of the tongue. By means of a special tongue-depressor and the laryngoscopic mirror, a very red, shining tumefaction was discovered at the base of the tongue, occupying the whole left half of the lingual tonsil, passing beyond the border of the epiglottis. It was considered advisable to make an incision, but before this could be done rupture took place during a violent spasm of the pharynx, and the throat was inundated by a flow of pus. The patient experienced a great relief, the deglutition of saliva became again easy, the pharyngeal pains less pronounced, and the voice clearer, and after three days the patient was completely cured.

THERAPEUTIC NOTES.

A Case of Intoxication with Bromoform.—VAN BOMMEL (*Deutsche medicin. Wochenschrift*, 1896, No. 3, p. 46) has reported the case of a child, ten months old, that took by inadvertence about a dram of bromoform. In a short time slight cyanosis had developed, the pupils were profoundly contracted and phenomena of respiratory and cardiac paralysis had made their appearance. The tongue presented a brownish discoloration, and the breath the characteristic odor. Artificial respiration was at once instituted, and the cutaneous surface was stimulated through hot bathing and cold douches to the head, the tongue meanwhile being pulled forward rhythmically. These measures were maintained for two hours, when an injection of ether was made. This was followed by trismus and spasms of the extremities. The injection was, however, repeated twice at intervals of half an hour, and gradually improvement began to set in. In the course of four hours respiration had become quieter and the cyanosis of the lips had given place to a red blush. In a day or two more, recovery was quite complete.

For Pulmonary Tuberculosis.—

EXCLUSION OF FOREIGNERS FROM THE PARIS MEDICAL SCHOOL.

By a recent decision of the faculty, foreign students are henceforth to be excluded from the Paris Medical School, and for this drastic measure the sole cause assigned is, "overcrowding." A considerable section of the French press has been loud in its outcry against this action of the faculty, and in deploring the sudden reversal of the broad and liberal policy which for centuries has characterized the management of the great educational institutions of the country. In France, however, it must be remembered that higher education, like the manufacture of matches, is a monopoly of the state, and that at the present juncture the action of the University may be in furtherance of the ultra-protectionist policy of the government. Another possible explanation is that the step has been taken with a view to filling once more the grass-grown courts of the provincial medical schools, which are still open to the foreigner, although unable (with two or three exceptions) to attract the native student. The spectacle presented by these almost deserted schools is deplorable. Their decay is chiefly attributable to the scheme of centralization, pursued in France by successive *régimes* for half a century, and which has made of Paris the only goal toward which ambitions tend. From time to time in these smaller schools a chair is suppressed for want of students (attendance at lectures being optional in French medical schools), and it is even alleged that in order to retain them the requirements of scholarship, nominally the same as in Paris, are indulgently modified.

That the school at the capital is overcrowded there can be no doubt. There are at present in Paris over four thousand students registered as attending the medical school, while the laboratory accommodation is inadequate for half that number. To relieve this congestion, an increase in the accommodation and teaching-staff is dismissed from consideration on the score of expense; adding to the requirements for matriculation, it is said, can be resorted to no more; while the suggestion to restrict provincial students to provincial schools for the first two or three years of the course has so far met with little favor. That the exclusion of foreigners will still leave the Paris school overcrowded is admitted by all, an admission which lends some weight to the theory that the blow is aimed at the practitioner from abroad rather than at the student. Many foreign graduates of the Paris school remain permanently there to practice, and in these days of keen competition the native practitioner cannot but regard their presence as an intrusion. To-day the cry is not "the more the merrier," but "*la France aux Français.*"

Emboldened by the recent action of the authorities, the Parisian students have already entered the breach, and demand that the French medical degree should in future confer upon the foreigners no privilege to exercise his profession on French soil. To this it may come, but probably more liberal counsel will prevail.

In conclusion a word may not be amiss as to the principal reasons for the present overcrowding of the Paris school. They are twofold:

Firstly, it is due to the remission in the term of military service accorded to those engaged in the study or practice of the liberal professions.

Secondly, to the tendency of the age, which leads the young man to abandon the country and

smaller towns for the great city, and in this special instance to seek to profit by the advantages of the largest medical school in the world, in the fond belief that his assimilative powers must needs be stimulated in proportion to the amount of pabulum set before him.

THE PRESENCE IN THE NORMAL THYROID GLAND OF A SUBSTANCE CONTAINING A RELATIVELY LARGE QUANTITY OF IODINE.

THE demonstration, by the distinguished Freiburg chemist Baumann,[1] of the presence of an organic iodine compound in the normal thyroid gland must be regarded as one of the most important of the recent contributions in the field of chemistry. But quite apart from the interest which belongs to it from a purely chemical standpoint, a much wider significance attaches to the discovery from its therapeutic aspects; for we are now at least promised a solid basis from which may be deduced an explanation of many well-known clinical facts which have been developed not only from the treatment of disease of the thyroid gland with thyroid extract, but from organotherapy in general.

Almost simultaneously with the earlier reports dealing with the benefits to be derived in certain diseases from the administration of the thyroid extract there developed in chemical circles an unprecedented activity in investigating the constituents of the thyroid gland; and the unabated interest which has since prevailed is evidenced by the large number of articles dealing with the subject that have appeared up to the present time. None of these, however, offers a satisfactory explanation of the beneficial influence which has undoubtedly followed this form of medication. The incomplete publications of Notkin, in which it was asserted that two substances—a protein and a ferment—were responsible for the virtues of the gland, have been looked upon, curiously enough, with favor by the French, although physiological chemists in Germany and America have not been inclined to consider them seriously. The crystalline nitrogenous derivative described by S. Fraenkel, although of chemical interest, is insufficient to supply a solution of the problem in question.

The idea that the element iodine might stand in some very definite relation to the metabolism of the thyroid gland is by no means new. Even as early as 1850 Chatin, who believed that iodine was present in the air, in water, in all plants, in fermented drinks, in milk, in eggs, and in the soil, suggested that its presence was essential to the welfare of the organism, and that cretinism and goitre occurred only in those regions in which iodine was entirely absent from the drinking-water. Others who studied the constitution of the air and of water denied, however, the presence of iodine in them, and Chatin's theory was at first discredited and afterward forgotten.

Kocher, the distinguished surgeon at Zurich, only a short time ago, relying upon the fact that the efficacy of iodine in the treatment of diseases of the thyroid gland compared favorably with that of the thyroid extract, suggested that the normal thyroid gland be examined thoroughly, in order to see if iodine existed in it. Tschirsch incinerated the gland, but failed to find iodine, and chemists, relying upon his results, naturally took it for granted that this element was absent. This negative result was perhaps not surprising, considering the small amount of iodine present in the crude gland, though Baumann has since detected it in the ash from one gram of the dried gland.

Roos, in a report of an investigation preceding Baumann's publication, in which he showed that the thyroid gland bore a distinct relation to the phosphorus metabolism of the body, mentioned some experiments which may really be looked upon as the forerunners of Baumann's brilliant discovery. It had for some time been known that digestion, moderate heat, and certain antiseptics did not destroy the active substances of the thyroid gland, and Roos proved, in addition, that prolonged boiling in 5 to 10 per cent. solutions of the mineral acids apparently did them no injury. It was his opinion that a portion of the active substance, though not all, was soluble in water.

Baumann, after boiling the glands in 10 per cent. sulphuric acid, and separating the fine flocculent precipitate after cooling, purified it by further

[1] *Ztsch. f. physiol. Chemie*, Bd. XXI, Heft 4.

treatment with alcohol and 1 per cent. caustic soda, and repeated precipitation with dilute sulphuric acid. He obtained a brown, amorphous substance, in weight from .2 to .5 per cent. of that of the fresh glands, and which, arguing from the results of Roos' experiments made upon men and dogs, he believed to represent approximately all the active principle of the gland. The substance is almost insoluble in water, very slightly soluble in alcohol, but easily dissolved in dilute alkalies, from which it is precipitated by the addition of acid. It yields no reactions for albumin, but contains always small amounts of phosphoric acid in organic combination. The most interesting fact concerning it is that it contains iodine, and that too in a relatively high percentage. Baumann reduced the substance to ash with caustic soda and nitrate of potash, dissolved the residue in water, added nitric acid, and shook with chloroform. A distinct violet color resulted, showing the presence of iodine. The work was done with pure chemicals, and the only possible source of the iodine was the substance obtained from the thyroid gland. To this substance Baumann has therefore given the name "thyrojodin." In his early experiments he thought that the preparation contained only about 3 per cent. of iodine, but after further purification he obtained a substance yielding as much as 9.3 per cent. of iodine; and he believes that when obtained absolutely pure it will show even a larger percentage of the element.

Baumann has been particularly fortunate in having the assistance of the large chemical factory of Bayer & Co., at Elberfeld, who prepared large quantities of the thyrojodin for his further experiments, more than 1000 sheep's thyroids being utilized for this purpose. At Freiburg, too, there is always available a large number of patients, drawn from the Black Forest and the Vosges, suffering from diseases of the thyroid gland, so that, with the active co-operation of Roos, Baumann was able to test the effect of the new substance clinically in human beings, a fact of much importance, since we now know that the thyroid extract is much more efficacious for human beings than for dogs and other experimental animals.

Thyrojodin is present in the thyroid of the pig, though in smaller quantities than in that of the sheep. It is probably present in the human thyroid; so far, Baumann has had the opportunity of examining only one human gland, a hardened pathological specimen, and this contained a small amount of iodine. If, however, as Baumann believes, the thyrojodin represents the whole of the active principle in the gland, it is difficult to see why it is that glycerine-and-water extracts of the thyreoid gland appear to be therapeutically perfectly efficacious, inasmuch as this substance is almost entirely insoluble in water. This apparent contradiction Baumann promises to explain in a subsequent publication.

That this discovery will throw new light upon the functions of the thyroid gland and upon the nature of the benefits of thyroidtherapy there can be but little doubt. Baumann suggests that the surprisingly rapid amelioration of symptoms in goitre which follows the exhibition of the thyroid gland itself, as compared with the results from the iodine treatment, may be due to the fact that whereas by the administration of simple iodine the manufacture of a certain substance is made possible and facilitated, by the employment of the thyroid gland or its extract, this same substance is brought into the organism ready-made and in a condition suitable for immediate metabolic use.

One of the most interesting features of the investigation is the demonstration of the marked elective affinity exhibited by a definite organ of the body for the element iodine. It is very remarkable, indeed, that a substance existing, as it must, in extremely small quantities in the blood and tissue fluids of the body can be accumulated in one organ and rendered thereby capable of elaborating in relatively large amounts a functionally active compound such as thyrojodin represents. It is quite possible, should Baumann's results be confirmed, that we have here to deal with a principle of wider application as regards the functions of organs, and the recognition of which would go far to throw light upon the whole subject of organotherapy.

The interesting physiological law formulated by Treviranus has already had clinical confirmation, at least for a number of organs. As a result of such work as that of Baumann, there

would seem to be some prospect of its establishment upon a definite chemical basis.

GENITO-URINARY AND VENEREAL DISEASES AND SYPHILOLOGY.

A CRITICAL RÉSUMÉ OF RECENT ADVANCE: SYPHILIS ACQUIRED IN ADVANCED LIFE.

Though in America and France it is generally admitted that syphilis contracted at an advanced age, as a rule, runs a rather severe course, and is frequently the cause of cerebral and cerebro-spinal lesions of varying gravity, it must be remembered that a number of German observers have reached a contrary conclusion. Thus, so sagacious an observer as the late Prof. Sigmund failed to find syphilis when developed in aged persons any more severe in its course and manifestations, or to be more frequently complicated with brain symptoms, than the same disease in the earlier periods of life. Sigmund's conclusions were based on the study of 118 cases of men and women in hospital and private practice, observed during a period of thirty years. Coming from such an eminent authority, this statement seems very striking; but when it is learned that the average advanced age in women was only 45 years and in men 55 years, our surprise is much diminished. In very many patients at this age the health is strong and vigorous, and senile decay has not yet set in. In striking contrast to Sigmund's views are those of Fournier, Quinquand and Ullmann, Rénault, Dulac and Regoby. In general it may be said that these observers held that the advanced age should be considered as periods between 50 and 70 years of life. In these ages they saw severe forms of syphilis, and noted the frequent occurrence of cerebro-spinal symptoms. Certainly this greater latitude for observation will yield far more trustworthy clinical results than a study of syphilis in middle-aged persons will. When it is remembered that syphilis expends its morbid action largely and extensively upon the blood-vessels, the fact strikes one that in old persons the severity of the attack is very much influenced by the condition of the vascular system. Upon the integrity of the patient's vessels, therefore, hinges in a large degree the greater or less severity of the syphilis. In old persons arterio-sclerosis is common, and may involve more or less of the circulatory apparatus. Instances of this involvement combined with syphilis are not at all uncommon. Besides vessel-changes, visceral lesions, general debility, an unstable condition of the tissues, and the systemic morbid effects produced by vicious habits and indulgences are undoubtedly factors of gravity in syphilis of advanced life. These reflections bring strikingly to the mind the futility of generalizations in the study of the question now under consideration. The truth is that the subject of syphilis in the aged should be yet gone over again by individualizing in each case, and on a large scale, before systematic conclusions can be drawn. The force of this contention has been well brought out in a discussion before the Berlin Dermatological Society upon the relative frequency of nervous affections in old persons attacked by recent syphilis (*Berlin. klin. Wochenschrf.*, No. 25, p. 551, 1895). In eleven cases between the ages of 61 and 64 years under his care, Born observed neither benignity nor malignity in the course of the disease, and in none was the nervous system attacked. In 600 cases of malignant syphilis Lewin only observed about 10 in which cerebral symptoms were present. Lewin's statistics are almost rendered nugatory for the reason that he included cases which had only passed their fortieth year. In this discussion Renvers hit the keynote of the question when he remarked that the evolution and course of the disease were especially influenced by the condition of the vascular system. A pre-existent encephalic arterio-sclerosis, according to the anatomo-pathological studies of this observer, was largely the determining cause of brain syphilis. Cases also are certainly seen in which an hereditary unstable condition of the nervous system has seemed to be the underlying cause of its involvement by syphilis.

Blaschko, in the same discussion, stated that he had been impressed with the mildness of syphilis in old persons, and had come to think that it was due to the great vitality enjoyed by voluptuaries who, when quite old, were capable of putting themselves in the way of contracting syphilis. Mendel, whose paper opened the foregoing discussion, thought that arterio-sclerosis was the underlying cause of the malignity of syphilis in the aged. A review of my own clinical

experience has convinced me that in many elderly persons of vigorous physique and good habits syphilis runs a comparatively mild course: in less vigorous persons it is more severe; but that in poorly nourished, weakly, and under-weight individuals, in nervous, excitable, neuropathic, and over-studious (brain-workers from all causes), it is often severe and even disastrous in its effects. Further, I have observed the malignant combination of arterio-sclerosis and syphilis and the grave effects of antecedent visceral diseases. Much further light can be thrown on this important and yet unsettled subject by the publication of well-observed cases.

ROBERT W. TAYLOR, M.D.

ECHOES AND NEWS.

IN compliance with a request from Secretary Chancellor, of the Association of Military Surgeons of the United States, Gov. Turney, of Tennessee, has appointed Brig.-Gen. T. C. Murrell, of Jackson, Surgeon-General; Col. E. Mills Willet, of Memphis, surgeon First Brigade, and Maj. J. R. Buist, of Nashville, surgeon First Regiment, as delegates to the sixth annual meeting of the association, which convenes in Philadelphia on May 12.

ARRANGEMENTS are being made by the Section of Neurology and Medical Jurisprudence of the American Medical Association, at their Atlanta meeting, in May, to have the medico-legal possibilities and bearings of the Röntgen rays upon medicine and surgery presented in an elaborately illustrated lecture. Several newly discovered facts will be stated, and unusual attention will be devoted to this topic.

THE *Lancet* announces that the late Lady Gregory, alias Mrs. Sterling, the celebrated English actress, has divided by will a large sum of money among several of the great London hospitals. In commenting on this it says that the theatrical profession have of late years been especially kind in the interest which they have taken in medical charities, and have shown it in a practical manner by often giving their services and lending their theatres for aid of hospital funds. It is needless to say that the theatrical profession of America is equally generous and beneficent.

SOME very interesting facts were recently brought out in a report to the Reichstag concerning the decline of disease in the German Army. From the report it appears that since 1868, when the number of cases of sickness was 1496 per 1000, there has been a steady reduction to 867 per 1000 in 1894, or 42 per cent., and the death-rate has gone down from 6.9 per 1000 to 2.4 per 1000, a reduction of 65 per cent., which means a saving of 2200 men each year. This remarkable improvement is due to modern improved hygiene and to the strict enforcement of vaccination during the past thirty years. Smallpox is now exceedingly rare, and has caused only two deaths since 1873. History demonstrates that the most devastating army epidemic is smallpox. In the French Army, during the Franco-Prussian war, there were 23,400 deaths from this disease, while in the German Army there were only 300 deaths. The campaign of 1870-71 reversed the time-honored rule that disease kills more than the enemy; 26,000 German soldiers fell in battle and 14,000 by disease.

THE statement is made that Kaiser William, of Germany, has had his left arm skiagraphed by the new process. This arm, as every one knows, is quite useless, and the skiagraph revealed the nature of the malformation. The result has been submitted to eminent surgeons, and it is stated that they believe a simple operation may give the Emperor partial, if not complete, use of his left hand and arm.

IT is reported in the daily press that Dr. Chantemesse, of Paris, has discovered an anti-typhoid serum, with which he has experimented on three patients. After the first injection they passed rapidly through the ordinary stages of the disease and became convalescent.

IN a recent conference between the New York State and New York City boards of health, a resolution was adopted asking that $300,000 be appropriated as a fund to be used in a systematic combat against tuberculosis.

AN appropriation recently made for a new public bath in New York city is certainly a charitable expenditure of the public funds along lines that must commend themselves to all. No other system of sanitation, either physical or moral, can be compared with the bath.

DR. HENRY P. WALCOTT, in a lecture delivered last week in Huntington Hall, Boston, Mass., upon "State Medicine in the Nineteenth Century," made use of the following statistics: Out of every 100 infants there die in the first year in Bavaria 30.6 per cent.; in Holland, 20.3; in France, 16.6; in Massachusetts, 16.3; in London, 16; and in Boston, 26.

BEFORE the Judiciary Committee of the Massachusetts Legislature, during its investigation relating to vivisection last week, Dr. W. T. Porter gave an interesting and detailed statement regarding the work of the Physiological Laboratory at Harvard from the first of last October to the present time. The lectures and demonstrations had been 128 in number, and the experiments on living animals 28, including 9 on dogs, 8 on rabbits, 5 on pigeons, and 6 on frogs. The dogs, rabbits, and pigeons were anesthetized throughout the operation. The dogs and rabbits were killed before consciousness was regained. In none of the experiments did the animals suffer.

THE *British Med. Journal*, Feb. 29, '96, announces the hope that the British government will shortly abolish all that remains of quarantine law in that country. It bases this expectation on the statement that plague and yellow fever are the only two diseases to which quarantine is now applicable in England; that the former has

been unknown in recent times in western Europe, that the danger is therefore very remote, and even should it appear it could be dealt with successfully by local government boards; while it had been demonstrated that yellow fever could be suppressed by the same instrumentality. Cholera, the one epidemic of the first gravity that has invaded the country in modern times, had been combatted successfully without invoking quarantine enforcement.

THE Dead-letter Office, at Washington, is said to still have in its possession a human skull, sent to the late Prof. S. D. Gross, of Philadelphia, eight years ago, and refused by him because there was $3.19 due in postage, the package having been sealed against inspection.

A SINGULAR society has been formed, taking the name of The Cornell Brain Association, which has for its object the post-mortem study of the effects on the human brain of education and good morals. At least we learn from the daily press that Dr. Wilder, of this association, has made another appeal to educated and moral persons to bequeath their brains to the institution for scientific study. In response to this letter the society has already received eight brains, and has the promise of twenty-five others, which are as yet being used by their owners. These latter include the brains of Thomas K. Beecher, of Elmira, and Mrs. McGee, daughter of the astronomer Simon Newcomb. Apparently no brains of immoral or uneducated persons can be used by the association, though it would seem that a few of the latter class might prove of advantage for purposes of comparative study.—*Boston Med. and Surg. Journal.*

DR. EDWIN A. BOWERMAN passed a recent civil-service examination at Albany, in which he attained the highest average, 95.3. He has been notified of his selection to fill the first vacancy as junior assistant physician in the New York State hospitals for the insane. Dr. Bowerman graduated with first honors from the College of Physicians and Surgeons of Baltimore in 1895.

INFECTIOUS bacteria are reported to have been discovered in Russian grain in great abundance, and with such tenacity of life that they withstand the heat of an oven. Germany is disposed to consider this sufficient ground for prohibiting the importation of Russian cereals, but a more careful investigation is now in progress.

A BILL has been presented to the Maryland Legislature providing for a board of dental examiners, from which all dentists entering the practice of their profession in that State shall be required to obtain a license.

THE College of Physicians and Surgeons, of Chicago, has purchased the post-graduate school and hospital adjoining the college, at Harrison and Honore streets, for $50,000. This will afford its students opportunities for practical ward work in hospitals not before permitted.

AT various places throughout the south and west smallpox is said to be present, but New Orleans is suffering from a real epidemic. Cases to the number of about twenty are discovered daily, and the pest-house was reported to contain already over 150 patients.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, March 3, 1896.

EDWARD D. FISHER, M.D., PRESIDENT.

A STUDY OF SPORADIC CRETINISM.

DR. WILLIAM B. NOYES read a paper with this title. He said that on September 1, 1895, he saw a child, 2 years old, who was not more advanced than a child of 6 months. The abdomen was protuberant, the nose short and retroussé, the tongue swollen and protruding, and the saliva dribbling from the mouth. There were two swellings on the neck, just in front of the sterno-mastoid muscles. The child appeared to be idiotic. Its length was 24 inches. The epiphyses of the long bones were somewhat swollen. There was no rachitic rosary or any other rachitic symptom. The mother stated that this was her first child, and that it had been born after a normal labor. Both parents were young and healthy. The child reached a weight of fourteen pounds after two months, and then did not gain for more than a year. The chief complaint had been constipation and weakness. There was no family history bearing on the condition. On September 15th the child was ordered a daily dose of one-fourth of a Burroughs & Welcome five-grain tablet of thyroid extract. By mistake a daily dose of five grains was given at first, with the result that the circumference of the neck was reduced two inches, and the child had begun to perspire. The temperature rose to 102°, and there were prostration and sleeplessness. At the end of a week the entire body had desquamated, leaving a clear, white, waxy skin. On November 24th, after having taken one grain daily, the amount of improvement was wonderful. By February the child had grown eight inches, and its weight had increased three or four pounds.

In considering the effect of heredity, the speaker said it might be manifested in three ways, viz.: (1) In a congenital local defect; (2) in a defect of growth; and (3) in a defect in the general vitality. One or more of these defects might exist in the same individual. Many epileptics, inebriates, and insane persons showed this physical and psychical taint. There was a very significant hereditary element in cretinism. Some European observers had believed the cretins to be the descendants of a degenerate race, but this could hardly be credited. Recent epidemics of cretinism had shown that heredity was the chief cause of sporadic cretinism. Only those whose parents had goitre seemed to develop cretinism. Those with goitres were not cretins, but cretinism appeared in the next generation. Endemic cretinism was not so much hereditary as a hereditary local deficiency. All over Europe, and particularly in the mountains, statistics showed that deaf-mutism was much more prevalent than in the lower-lying regions. This was probably due to the evils of consanguinity, poverty, and unsanitary surroundings. There were certain cretins who did not present all the typical indications of cretinism. In various parts of the world were to be seen cases presenting the general features common to endemic cretinism, which were known as sporadic cretin-

ism. In early childhood these cases had been frequently confused with the more common forms of idiocy. When the thyroid gland is removed by operation, or when it atrophies from disease, certain changes are observed. First, there is a general disturbance in the nutrition and the development of myxedema—a general increase in the bulk of the body, a deposit of infiltration of mucin. The latest examinations by Halburton showed a practically normal percentage of mucin in the skin, and a very slight increase in the subcutaneous tissues. There was an excess of "basement substance," or young connective tissue holding mucin. In the later stages of myxedema the subcutaneous connective tissues became permeated by white fibres and fat-cells—the atrophic stage. The blood is altered, and there is some evidence of toxicity in the blood. Acute or operative cases in animals showed certain nervous symptoms, such as fibrillary tremors or convulsions. In the young infant the myxedematous process tended to produce: (1) a condition of idiocy; (2) edema and swelling of the subcutaneous tissues would be more marked than in the adult, because the tissues were softer; and (3) a general change occurred in the bony framework of the body—*e.g.*, a peculiar shape of the skull, lordosis of the spinal column, and a general dwarfed appearance. In the long bones of cretins the almost geometrical relation of the rows of ossifying cells found in the normal condition gives place to irregular cells, and growth in the longitudinal direction is stopped. At some of the autopsies, fibrous connective tissues had been found around the epiphyses. Rachitis was a very different process from that seen in cretinism; the cartilage cells proliferated rapidly and very irregularly, and ossification was irregular and failed entirely. Hofmeister removed the thyroids from a number of rabbits. They developed only very slight symptoms, but those operated upon were soon noticed to be smaller than the control animals, their bellies were more protruding, and their skulls broader. After from two to seven months they were killed. Few changes were found in the soft parts; there was no myxedema and no special changes in the viscera. There was a decided retardation in the development of bone in the thyroidectomized animals; the skull and jaw were the least affected. There was a difference in growth of one-third in the tibiæ of the thyroidectomized rabbits and the control animals. The case of a boy had been reported, from whom the thyroid had been removed when he was 10 years of age, and who had not grown at all during the eighteen months that he survived the operation.

The etiology of sporadic cretinism was even more obscure than that of the epidemic form. Of the reported cases, several seemed to have been the first children of quite young parents; one or both of the parents were apt to be neurotic; there was often a marked alcoholic taint; there were other children in the family with some other nervous disease or possessing some stigma; and in Edinburgh the prevalence of cretinism was apparently due to squalor and poor food and air.

In conclusion, the speaker emphasized the following points: (1) That the symptoms of cretinism were to be explained as a result of a myxedematous process in the undeveloped tissues of the infant; (2) the scientific application of the principles of heredity, by such methods as had been used in deaf-mutism, idiocy, and other nervous diseases, would yield similar results in cretinism.

Dr. W. M. Leszynsky said that he had had under his care a cretin, 25 years of age. It was a case of sporadic myxedematous cretinism, and the mental development was so defective that the man acted like a child of 6 years. There was an absence of thyroid, and there was some myxedema. The man was treated in the hospital for a number of weeks by the thyroid extract, with but very little benefit.

Dr. L. Seigleitz said that Ewald in his most recent study of myxedema and cretinism had not been able to accept the thyroid theory alone as the cause of cretinism. He adduced a number of good reasons for believing that this was not the only etiological factor. He thought the excellent result in the case just reported was due to the fact that the child came under treatment at a very early age. It was hardly to be expected that the older cases would respond quickly to the treatment. An interesting point about the development of cretinism was that very many of these children appeared to be perfectly normal until about the time of weaning. This could be explained by the fact that animals who fed on vegetables and milk did not develop myxedema nearly as rapidly as animals fed on flesh.

The President said that it was now pretty well established that sporadic cretinism occurred chiefly among the poor and amid unsanitary surroundings. The photograph of Dr. Lezaynsky's patient closely resembled one of a family of three cretins living in this city. They were typical cretins, and they had given absolutely negative results from the thyroid treatment. He had seen a considerable increase in the intelligence even in patients of 40 years. There could be no question about the excellency of the results from the thyroid treatment if the child came under observation at the age of 2 or 3 years. Goitre, he said, was widely distributed through certain portions of Canada, yet in persons so afflicted he had never observed any tendency to cretinism or exophthalmic goitre.

Dr. Noyes said that he had desired in his paper to direct attention to the great importance of grasping all forms of stigmata. He recalled an article in which had been stated that among the French-Canadians sporadic cretinism and goitre were common.

A CONTRIBUTION TO THE STUDY OF ACUTE ASCENDING (LANDRY'S) PARALYSIS, WITH EXHIBITION OF SPECIMENS STAINED BY THE NISSL METHOD.

Dr. Pearce Bailey said that the labor of preparing this paper had been equally shared by Dr. James Ewing and himself. Although it was nearly forty years since Landry described the disease which bore his name, there were to-day conflicting views regarding its pathology. The symptoms of the original case had been acute paralysis ascending from the legs and arms, unaccompanied by marked loss of sensation, or by involvement of the sphincters. The intellectual faculties remained unimpaired.

After death no lesions were found in the nervous system to explain these symptoms, and careful microscopical examination of the spinal cord by several observers was absolutely negative. The nerves were not examined.

The authors of this paper said that they had recently seen a case of acute ascending paralysis with extensive lesion in the spinal cord. The patient, a female, 36 years of age, was admitted to the Roosevelt Hospital, November 25, 1895, to the service of Dr. Francis Delafield. The family history was negative. The patient had previously enjoyed good health. On November 19th the disease began with vomiting, which continued until the third day, when she went to bed exhausted. She then began to have occasional attacks of vertigo, and dimness of vision. On November 23d she suddenly lost the power of both legs, and the next day there was paralysis of both arms. Sensation was undisturbed. The temperature was 101.4 at the time of her admission, and the urine examination was negative except for finding a few hyaline casts. The only important point in her personal history was that she had been a rather excessive beer-drinker. There was moderate ptosis on the left side; tactile sensibility was normal; there was no pain or tenderness in arms and legs; the bladder control was normal; the knee-jerks were lost; there was diminished response of the paralyzed muscles to the faradic current. On the 27th she complained of headache and dyspnea; on the 29th the urine contained a trace of albumin; and on the 30th, after a severe attack of pulmonary edema, she died. At the autopsy, which was made twenty hours after death, the serous cavities were normal; the lungs were moderately congested; the bronchial lymph-nodes were normal. The muscle of the heart was rather pale, and there were a few atheromatous patches in the aorta. The liver was reduced in size, and the general outline of the lobules was indistinct. The spleen was large and rather firm; its trabeculæ were faintly visible, and the Malpighian bodies imperceptible. The kidneys gave evidence of acute degeneration. Examination of the brain showed considerable distention of the veins and sinuses; there were no thrombi. Sections disclosed a large but not distinctly abnormal blood content. The consistence of the spinal cord was normal: the white matter appeared normal; the gray matter was plainly outlined and very slightly congested. The anatomical diagnosis was congestion and edema of the lungs, acute degeneration of the kidneys, acute hyperplastic splenitis. In the microscopical examination the Nissl stain furnished the most satisfactory result of the many stains tried. It is excellent for studying the changes in the ganglion cells. The vessels of the cauda equina were filled with blood; the axis cylinders of the nerve fibres appeared to be normal. The nerve fibres in the nerve roots appeared to be normal; in some nerve roots there was a slight perivascular infiltration of small round cells. Examination of the spinal cord showed the gray matter to be extensively affected throughout the entire length of the cord; there was intense congestion of all the blood-vessels, especially of the anterior branches of the spinal artery. Nearly all the vessels showed pronounced perivascular infiltration of small round cells. There was a diffused cellular infiltration of the gray matter, at times extending slightly into the white matter. The central canal appeared not to be especially affected. There was a more or less complete absence of chromophyllic masses in the cells. In some cells the cytoplasm was entirely bereft of chromophyllic bodies, being replaced by fine bluish particles. In the areas where the exudative inflammation was most pronounced, many shrunken cell bodies without visible cell nuclei were recognized with difficulty. In the white matter, where the inflammatory process extended into it from the gray matter, there was moderate perivascular infiltration. In the cervical region of the cord the lesions were most pronounced, while in the sacral region they were the least, many ganglion cells in the anterior horns remaining fairly well preserved. The lesions in the medulla and pons were chiefly marked in the gray matter, and were similar to those described in the cord. The nuclei of the cranial nerves were all more or less damaged, but chiefly in the sixth or seventh nerves. The basal ganglia showed the perivascular lesion and numerous small foci of cellular infiltration. The tempero-sphenoidal lobes were normal. Throughout the cerebellar cortex were found lesions similar to those found in the spinal cord. In the case just reported the clinical symptoms were attributable to most extensive lesions affecting chiefly the gray matter of the spinal cord. The fact that the lesions were but slight in the sacral region explained the persistence of sphincter control.

There were many recorded cases, the speaker said, in which an ascending paralysis, unaccompanied by sensory symptoms, soon involved the bulbar nuclei. An ascending paralysis, pursuing a rapidly fatal course without pronounced sensory symptoms, was a distinct clinical entity. These had always been considered the essential symptoms of Landry's paralysis.

To this paper was appended a table of all the carefully recorded cases, except those published in the Russian and Scandinavian languages and a few old monographs. Several cases had been included which had been hitherto described as acute poliomyelitis anterior.

Fatal acute ascending paralysis might be divided into the following groups: (1) Cases in which no histological changes could be demonstrated in the nervous system; (2) those in which there was an acute exudative inflammation of the cord, medulla, and sometimes of the brain; (3) acute inflammation of the peripheral nerves; (4) acute inflammation, both of the central and peripheral nervous systems. In sixteen of the collected cases there were lesions limited to the cerebro-spinal axis. A consideration of the etiology, symptoms, and pathology of the disease points to the action of a toxic agent as the direct cause of the lesions. The lesions indicated an acute exudative inflammation, such as is usually found in cases having a bacterial origin. The authors had found it impossible to differentiate these various groups by their clinical manifestations. Their conclusions were: (1) That acute ascending paralysis was probably a toxemia in which the poisonous agent affected chiefly the nervous system; (2) that its most common seat was in the spinal cord or medulla, though it might be present in the cortex

and nerve roots; (3) that the lesions in other parts of the cerebro-spinal axis were of a similar nature; and (4) that when the lesion affected the peripheral nerves there was an increase of neuroglia cells.

Dr. Beverley Robinson said that he had seen only one case of this disease, and that one had been reported some time ago to the Practitioner's Society. In the clinical history of that case there was no evidence of any toxemia. The pathologist who had charge of the case failed to examine the nervous system by the improved methods detailed in the paper, or by bacteriological methods, but he reported that there was little or no evidence of lesion in the spinal cord, although there were some pathological changes in the nerves themselves. The case had run a rapidly clinical course, and the patient had died of edema of the lungs.

Dr. C. L. Dana said that as he recalled Dr. Robinson's case the clinical history was clearly one of Landry's paralysis, but there were no careful microscopical or bacteriological examinations reported; hence, though the case was apparently some form of toxic neuritis, there was no proof that the nerve cells were not primarily implicated. Three years ago when discussing the subject with Mr. Victor Horsley the opinion had been expressed that paralytic rabies might be classified clinically as Landry's paralysis, and that probably some of these cases were really examples of rabies. The sections at present under the microscope showed some cellular changes, yet the general pathological picture was that of a very marked vascular trouble—an infection or toxemia. He would say most certainly that the primary changes were vascular, and those in the ganglion cells were secondary. His experience with the Nissl stain had led him to place much less confidence in its revelations than did many others. In almost any brain one could find all sorts of changes in the chromophyllic substance, and the method of preparing the staining and sections made it seem to him almost impossible that there should not be considerable differences in the way in which the various cells took up the coloring substance. The cortex cells in this specimen seemed nearly normal, although there was here evidence of this same vascular irritation. He thought that if the nerves had been examined it would have been found that they had been damaged even more than the nervous system. He recalled a case resembling Landry's paralysis, although running a slower course, in which there had been evidence of nervous and vascular irritation; the history of the case showed it to be rapidly fatal alcoholic neuritis.

Dr. B. Sachs said that Landry's paralysis had been buffeted about a great deal by various writers. Fortunately the day had passed when diseases were classified entirely on mere topographical lines. That there was a toxic agent causing Landry's paralysis he thought there could be no doubt, and hence it was to be particularly regretted that a bacteriological examination had been omitted in this and many other cases. Since the bacilli of influenza had been found in cases of spinal-cord affection following that disease, it became incumbent on every careful observer to make a bacteriological examination. He also felt that we should be very careful in making inferences regarding slight changes in the structure of the cells in specimens stained by Nissl's method. In the case reported in the paper, one of the chief symptoms had been absence of sensory disturbance quite early in the disease. If this one clinical feature must be accepted as essential we could not suppose that the changes which had been described were those chiefly responsible for Landry's paralysis. It was more than probable that the changes occurred not only in the brain, but in the spinal-cord and the peripheral nerves.

Dr. George Jacoby said that if we accepted Landry's definition of the paralysis we could only make a clinical diagnosis, for Landry claimed that there must be a lack of anatomical evidence. He had been struck by the fact that in the case described in the paper the patient was a beer-drinker, and that the symptoms had developed quite rapidly. This had been noted in quite a number of cases. The lesion might be localized in the cells of the spinal cord or in the cortex. The report presented seemed to indicate that in the future we would probably find pathological changes in the cell body analogous to those which had been thus far found in the peripheral nerves. It would seem that we were dealing with a chronic alcoholic intoxication of the central nervous system.

Dr. Landon Carter Gray said he thought that the paper just presented was an extremely valuable contribution to the subject of Landry's paralysis. He could recall a number of cases of this disease which could be divided into several groups. Some of these had proved rapidly fatal; some had run a slower course; some had improved and then relapsed. Those which had recovered had subsequently had atrophy of the muscles, and had presented a condition similar to that of poliomyelitis. He had also seen cases of alcoholic neuritis presenting several types—some few had died, some had had obstinate vomiting for days and weeks, some had passed into a miserable condition of invalidism. He could not recall that any of these cases had recovered. The clinical definition of the disease could not be taken as anything more than a guide. Undoubtedly there was an underlying toxemia, and possibly an infection. It seemed to be pretty generally agreed that Nissl's stain was still on trial, and certainly some very serious objections had been made to it, so that our deductions based upon it must be made with great caution.

Dr. Joseph Collins said that the paper just contributed had served to crystallize what had been in our minds—*i.e.*, that Landry's paralysis had been handicapped by a name and a tradition which for years had prevented us from forming a legitimate conception of the pathology of the disease. All must have been impressed with the fact that Landry's paralysis was a disease dependent upon a poison, and that its clinical forms varied as to the part of the nervous system implicated. It had not yet been proved that the disease was one of the spinal cord or of the peripheral nervous system. When it had been said that Landry's paralysis was a disease dependent upon infection, or upon a toxic substance manifesting its action on a well-defined part, or on the entire nervous system, the pathological location of the disease, so far as known, had been stated. In the case reported in the paper the

lesions were universal, hemorrhagic splenitis, parenchymatous nephritis, and an exudative inflammation in the spinal cord, all of which pointed to an infection. The changes in the cord were virtually those of acute anterior poliomyelitis, a disease which was very probably due to some micro-organisms. The underlying condition should not be described as a "toxemia," which meant a primary blood inflection, but as toxic. If epidemic cerebro-spinal meningitis and acute anterior poliomyelitis had been shown in a number of instances to have been associated with pyogenic micro-organisms, why should not Landry's paralysis be dependent upon such a condition also?

DR. SACHS said that in almost every case in which the disease had been named after a person who had first described it an unusual reverence had been shown for the symptomatology first reported. Thus, Landry had insisted that there should be bulbar complication, yet this was more or less accidental, although present in most of the cases. It would not be right, it seemed to him, to exclude all those cases in which the process had not extended into the medulla, provided the other symptoms were those of acute ascending paralysis. It would be better to speak of the disease under discussion as an acute infectious ascending paralysis.

THE PRESIDENT said that it seemed to him that the so-called Landry's paralysis was an acute infectious process, which at times affected the spinal cord, and at other times affected the nerves to a greater extent. He could not see how it at all resembled the ordinary cases of even the most acute alcoholic multiple neuritis.

DR. JAMES EWING thought the Nissl stain had been very generally accepted as the best method of studying the pathological changes in the ganglion cells. Dr. Dana's trouble with this stain was probably due to the use of alcohol as a hardening agent; the cells should be treated with bichloride of mercury. The examination of the cauda equina and the nerve roots in this case seemed to absolutely negative the opinion expressed by Dr. Dana that in the nerves, if examined, would have been found even more pronounced changes. We would have to assume that the central nervous system and the peripheral nerves were markedly affected, and yet the intervening portion—the nerve-roots—had escaped. In the case reported, sensory symptoms were almost entirely absent. A careful examination of the literature showed that cases of acute multiple neuritis resembling Landry's paralysis were exceedingly rare. The word "toxemia" had been used advisedly in the paper, for the authors were not ready to state that Landry's paralysis was an acute infectious disease. They used the word "toxemia" because they believed the disease was produced by a toxic agent in the blood which, at least in some cases, was of a bacterial nature.

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE MONTH ENDING JANUARY 31, 1896.

GARDNER, C. H., Assistant Surgeon. Ordered to examination for promotion January 4, 1896. Granted leave of absence for thirty days, January 15, 1896.

NYDEGGER, J. A., Assistant Surgeon. Ordered to examination for promotion, January 8, 1896.

WIEKES, H. W., Assistant Surgeon. To proceed from New Orleans, La. to Memphis, Tenn., for temporary duty, January 14, 1896.

BANKS, C. E., Passed Assistant Surgeon. To proceed from Washington, D. C., to Boston, Mass., for temporary duty, January 31, 1896.

PETTUS, W. J., Passed Assistant Surgeon. To assume temporary command of Service at Norfalk, Va., January 31, 1896.

GUITERAS, G. M., Passed Assistant Surgeon. To proceed from Gulf Quarantine to Mobile, Ala., for temporary duty, January 18, 1896. To rejoin Station at Gulf Quarantine, January 31, 1896.

STEWART, W. J. S., Assistant Surgeon. Granted leave of absence for ten days, January 27, 1896. Ordered to examination for promotion January 31, 1896.

SPRAGUE, E. K., Assistant Surgeon. Granted leave of absence for twenty days, January 23, 1896.

PROCHAZKA, EMIL, Assistant Surgeon. To proceed from Detroit, Mich., to Chicago, Ill., for temporary duty, January 31, 1896

WISKES, H. W., Assistant Surgeon. Upon completion of temporary duty at Memphis, Tenn., to return to his station at New Orleans, La., January 17, 1896.

RESIGNATION.

GOODWIN, H. T., Passed Assistant Surgeon. Resignation accepted, to take effect March 5, 1896.

BOARD CONVENED.

Board convened to meet in New York city for the physical examination of candidates for appointment in Revenue Cutter Service. Sergeon W. A. Wheeler (Chairman), and Assistant Surgeon H. S. Cumming (Recorder), January 29, 1896.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 4, 1896, TO FEBRUARY 24, 1896.

The leave of absence on surgeon's certificate of disability, granted Captain William O. Owen, Jr., Assistant Surgeon, U. S. Army, is extended one month on account of sickness.

First Lieutenant William W. Quinton, Assistant Surgeon, will be relieved from duty at Fort Riley, Kansas, and ordered to Fort Logan, Colorado, for temporary duty.

Captain C. N. Berkeley Macauley, Assistant Surgeon, died February 6, 1896, at Fort Logan, Colorado.

Major Joseph B. Girard, Surgeon, will be relieved from duty at the Presidio of San Francisco, Cal., and ordered to Jefferson Barracks, Missouri, for duty at that post, relieving Major Robert H. White, Surgeon.

Major White, upon being relieved from duty at Jefferson Barracks, will proceed to Presidio of San Francisco, Cal., for station.

First Lieutenant William W. Quinton, Assistant Surgeon, is relieved from temporary duty at Fort Logan, Colorado, and ordered to Fort Grant, Arizona, for duty at substation San Carlos, Arizona, relieving First Lieutenant Paul F. Straub, Assistant Surgeon.

Lieutenant Straub on being thus relieved, is ordered to Angel Island, Cal., for duty at that station, relieving First Lieutenant Charles E. B. Flagg, Assistant Surgeon.

Lieutenant Flagg upon being thus relieved, is ordered to Fort Du Chesne, Utah, for duty at that post, relieving Captain Henry D. Snyder, Assistant Surgeon.

Captain Snyder, upon being thus relieved, is ordered to Fort Ethan Allen, Vermont, for duty at that station.

CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, FROM FEBRUARY 7, 1896, TO FEBRUARY 22, 1896.

February 7.—LOWNDES, C. H. T., Passed Assistant Surgeon, detached from marine rendezvous, San Francisco, and granted one month's leave.

BAGG, C. P., Assistant Surgeon, detached from the "Vermont," and ordered to the marine rendezvous, San Francisco, Cal.

ORIGINAL ARTICLES.

TYPHOID FEVER AS A COMPLICATION AND A SEQUEL OF INFLUENZA.[1]

By J. M. ANDERS, M.D., PH.D.,
OF PHILADELPHIA;
PROFESSOR OF MEDICINE AND CLINICAL MEDICINE AT THE MEDICO-CHIRURGICAL COLLEGE; PHYSICIAN TO THE PHILADELPHIA AND MEDICO-CHIRURGICAL HOSPITALS, PHILADELPHIA.

DURING the recent epidemics of influenza, the first of which occurred in the latter part of 1889, I observed cases of influenza that apparently developed into pure typhoid fever. Two instances of this sort I reported elsewhere.[2] In my former paper a brief allusion to some statistics, which showed that out of 338 cases of influenza 6 were complicated with typhoid fever, was made. In one of these typhoid developed after an interval of normal temperature lasting twenty days. Three additional cases, two of which occurred in the practice of Dr. J. N. Snively, are reported below.

Reference is not had here to the rather numerous instances of influenza with marked intestinal symptoms that more or less strongly resemble typhoid fever. Da Costa has recently reported a case of the latter sort.[3] These can, as a rule, be easily separated from typical forms of typhoid fever. Thus, in Da Costa's case, the appearance of the tongue (dry, and red at the tip), the swollen belly, and the marked general debility in the absence of localized inflammatory lesions, pointed to typhoid, but the presence of a markedly irregular temperature record, on the one hand, and the absence of either enlargement of the spleen or the typhoid eruption, on the other hand, showed the case to be one of influenza of adynamic type.

The chief object of the present paper is to confirm the statement made elsewhere that typhoid fever may appear as a late complication of influenza, or may follow this disease.

Among other affections which are known to be associated with la grippe, as complications in varying degrees of frequency, are: pneumonia, both croupous and catarrhal (with which latter disease pleurisy is always, and purulent pericarditis rarely, combined); gastro-enteritis, cerebro-spinal meningitis, etc. Again, its most common sequelæ are phthisis, peripheral neuritis, perineuritis, melancholia, mania and neuralgia.

Cases of influenza which are complicated with typhoid fever are confessedly difficult of correct diagnosis without careful bacteriological studies. I do not doubt that their dual nature has often escaped recognition. At all events, they have not been added to the literature of the subject previous to the appearance of my own article, so far as I know.

No bacteriological observations were undertaken, either in connection with the cases reported previously or those herein narrated; hence, the evidence to show the clinical association of these two diseases has been gained only by observation of the symptoms at the bedside.

CASE I.—E. S., male, aged 22, a student, was taken ill Feb. 20, 1895. The onset was sudden. There were repeated slight chills, followed immediately by fever; intense headache; pains in the muscles generally, and great languor. The following day I was called to his boarding-house, where he had betaken himself to bed. The following condition was presented:

Great prostration; intense headache, the pain being situated especially deep in the orbits and in the region of the occiput. Temperature was 102° F.; pulse, 100 per minute; great pain in muscles of limbs, loins, and the intercostal spaces. The following day, as a result of the action of a purgative, he experienced severe gastro-intestinal pains with marked diarrhea. The latter symptoms were soon controlled by the use of paregoric and intestinal antiseptics. There was now some sore throat, tickling of the pharynx and considerable dyspnea, but not much cough; nor were there any abnormal physical signs referable to the chest. His spleen was at this time not enlarged The diagnosis of influenza was readily made.

The course of the case for the next five or six days also fully corroborated this view. During the latter period the intense headache persisted. There was the usual restlessness, together with utter muscular prostration, and the burning and boring muscular pains, which changed their seat in the manner so frequently observed in la grippe. The fever continued and was of irregular type, and the pulse was increased in frequency proportionately with the fever. At the end of the latter period, or about the time that

[3] "Cases of Influenza Simulating Typhoid Fever and Cerebro-Spinal Meningitis," *University Medical Magazine*, Philadelphia, Feb., 1894.

defervescence in the temperature was expected, the evening temperature continued at 103° F., and the morning ranged from 101° to 102° F. The spleen now was slightly enlarged, the abdomen slightly tender, especially in the ileo-cecal region; and there was slight diarrhea, amounting to two or three soft, ochre-colored stools daily. No new nervous symptoms had appeared, but the very severe headache showed little tendency to abate. The catarrhal symptoms, referable to the nose and throat, however, had completely subsided.

March 3d.—Typhoid fever was now suspected. On March 4th (the twelfth day of the illness) the temperature was still pursuing the same continued type. The spleen was found, on palpation, to be considerably enlarged, and there appeared two characteristic typhoid spots on the upper part of the abdomen. The rose-spots faded away in the usual length of time, and subsequently a fresh and more abundant crop put in an appearance. The case was now treated as one of typhoid fever, to wit: by allowing a liquid, nourishing diet, by the use of cool baths, and internally quinine and salol in combination.

Apart from the fever, no other symptom demanded therapeutic measures save the headache and neuro-muscular pains, the latter affecting especially the loins and lower intercostal spaces. While the physical signs were negative, the patient was unable to take a deep inhalation at any time during the attack without experiencing pleurodynic stitches. These pains subsided with the decline of the temperature, and the subsidence of the typhoid symptoms—events which began at the end of the fourth week of the illness. Defervescence by lysis, so characteristic of typhoid, followed.

For the notes of the two instances following I am greatly indebted to Dr. I. Newton Snively, in whose practice the cases occurred.

Case II.—"I was called, Feb. 28th, 4 P.M., to see Mr. A. W., aged 42 years, who reported to me that while at work (as brass-finisher), one hour before my visit, he was suddenly seized with a chill of moderate severity, soon after which he began sneezing and coughing. He developed speedily severe headache, pains in the muscles of the limbs and trunk, and soreness all over the body. At the time of my visit his temperature was 103° F.; pulse, 100; respiration, 24. He had, thus early, a naso-pharyngeal and bronchial catarrh. The heart was acting strongly and regularly. The patient gave a history of having felt well up to within an hour of the chill. During the three succeeding days he was much depressed in spirits; he was restless and wakeful at night; also, complained of nausea and loss of appetite. The bowels were regular.

"Under the usual influenza treatment he rapidly improved, temperature fell to normal on the fourth day, while the cough and myalgic pains were now, also, completely relieved. Appetite was restored, and the patient apparently in a comfortable condition, so that I discharged myself, with the instructions to the family and patient to send for me in case convalescence was in any way interrupted.

"March 7th, two days after I had dismissed myself from the case, I was sent for in the afternoon to see the patient again. I now found him with a temperature of 100° F.; pulse, 90; respiration, 22; and complaining of pain and tenderness in the abdomen, bleeding from the nose, and occipital headache. On physical examination I found the spleen slightly enlarged, the abdomen tympanitic, the tongue heavily coated, the mouth dry, the pupils dilated, and the patient quite restless, but there was no delirium. The nurse reported six loose movements of the bowels during the previous 24 hours.

"From this time on the patient advanced rapidly into characteristic typhoid fever. The temperature curve became very characteristic, the epistaxis grew worse and become so unmanageable that I plugged the anterior and posterior naries on March 9th. The typhoid eruption appeared extensively on the latter date; the diarrhea persisted; the heart became weaker in action and the sounds more feeble; the respirations hurried, and there was a slight cough, with a few bronchial râles on ausculation. His expression grew very dull and heavy, and the cheeks were flushed. The tongue became very tremulous; it was very dry and brown, and sordes collected on the teeth. Headache became very severe; there appeared moderate deafness, stupor, muttering delirium, picking at the bedclothing and imaginary objects.

"Dr. J. M. Anders saw the patient with me on March 9th and confirmed the diagnosis of typhoid fever. He also thought the case had been one, primarily, of influenza, followed by typhoid. I saw the patient on the morning of March 10th, when the nurse gave a rather favorable report, as the patient had slept more than any previous night for a week; his pulse was dicrotic but regular, and marked 112; temperature, 102.5° F.; patient taking milk and whisky regularly and in proper quantities; nose-bleed controlled by plugs; mouth kept moist by placing a large flat sponge (moistened frequently) over it. One hour after my visit I was again summoned to the case, and, upon entering the room, found the patient dead. The nurse, who was an experienced graduate, reported that the patient had suddenly stiffened himself in bed, and when she took his pulse she found it had gone up to 160, was irregular and very weak; that the patient seemed to be in a faint. She administered carbonate of ammonium and gave a hypodermic of strychnine and digitalis, but with no effect, as the patient died a few minutes later. One hour after death large quantities of blood passed from the bowels, thus showing that the patient had died of an internal

hemorrhage. He had shown the hemorrhagic diathesis from the first inception of the typhoid fever. No autopsy was made."

CASE III.—"Mr. J. L., aged 20 years, Canadian by birth, sent for me Feb. 23, 1895. He complained of severe pain in the substernal region, and sharp myalgic pains about the chest. He had a severe cough, paroxysmal and painful in character; he also had acute coryza; he expectorated a scanty, tenacious mucus; his temperature was 102° F.; pulse, 96; respiration, 23. On physical examination, I found a few irregularly distributed subcrepitant râles. The respiratory murmur was feeble. The tongue was coated; appetite poor; bowels were regular, and the abdomen normal. He had severe headache, and was very restless at night, but not dilirious. Was very weak and perspired profusely. He told me he had been working regularly every day, and felt well until this attack came on. He was employed as a stone-carver, and, at the time he was taken sick, was working on the outside at the Bourse building. I saw him every day for four days, when his catarrhal symptoms, fever, and cough subsided. He now sat up out of bed and felt comparatively well, except that he was very weak and languid.

"March 3d I was again summoned to the patient with the report that he was suffering with severe abdominal pains, diarrhea, and vomiting. This was five days after I had made my last visit to him for the influenza.

"I found him with a heavily coated tongue; complete anorexia; distended and tender abdomen; temperature, 101° F.; pulse, 90; respiration, 20. I ordered a salol and bismuth mixture, and put him on a liquid diet. From this time on he passed through a characteristic attack of typhoid fever; temperature higher each day than the preceding, at first, and always higher in the evening than in the morning. The small, slightly elevated, rose-colored spots appeared on the abdomen on the 10th of March, and the spleen was manifestly enlarged. He had the characteristic nervous symptoms—headache, stupor, twitching of tendons, etc. The urine was small in quantity and very slightly albuminous. Convalescence set in after an illness of twenty-eight days, and was marked by falling out of the hair, anemia, etc."

In my present and previous articles are contained the notes of five cases in which typhoid fever was either a complication or a sequel of influenza. It cannot, in view of the statistics before quoted, be claimed with justice that typhoid fever is a frequent complication or sequel of la grippe. That the epidemic prevalence of influenza is attended with an increased number of cases of typhoid fever, however, is also shown by tracings, which appear in my first article.[1] I am of opinion that further observation of influenza, with special reference to its association with typhoid fever, will confirm the dictum that the occurrence of the former disease renders the body more than ordinarily receptive to the typhoid bacillus.

DISEASES OF THE ACCESSORY NASAL SINUSES, WITH SUGGESTIONS REGARDING THEIR TREATMENT.[1]

BY ROBERT CUNNINGHAM MYLES, M.D.,
OF NEW YORK;
PROFESSOR OF OTOLOGY AND ADJUNCT-PROFESSOR OF RHINOLOGY AND LARYNGOLOGY AT THE NEW YORK POLYCLINIC; SURGEON TO THE NOSE AND THROAT DEPARTMENT OF THE CHURCH HOSPITAL AND DISPENSARY; ASSISTANT SURGEON TO THE NOSE AND THROAT DEPARTMENT OF THE NEW AMSTERDAM EYE AND EAR HOSPITAL.

SECOND PAPER.

THIS paper may be considered a continuation of the one I read before this section in January, 1893,[2] and contains a further record of my experience with diseases of the accessory nasal sinuses. I am aware that the subject has been worn almost threadbare and that many assertions and opinions have been advanced regarding it; but it is my hope, by furnishing details of my work, and the rational deductions therefrom, to assist in placing some of these assertions upon a scientific basis. First, a correct diagnosis; and, second, the best treatment to be employed, are the things for which we should strive. Previous to ten years ago, not 5 per cent. of these cases were correctly diagnosed. Now I may safely say that from 20 to 80 per cent. are detected—the percentage, of course, depending upon the care and energy of the investigator, and the methods he employs. Concerning proper methods of treatment, our opinions must be based upon the results obtained by earnest and capable operators.

In regard to diagnosis. The electric lamp, though often deceptive, is very valuable, especially in antral affections. A unilateral umbra on the lower conjunctiva, with absence of crescentic illumination on the lower lid, and absence of the perception of light when the eye on the same side is closed, will in almost every case, especially if the patient is a blonde and moderately thin, prove to be due to some abnormal condition of the antrum, probably an empyema. I repeat the words used in my last report, that "the electric light is not infallible, but invaluable to one who knows how to use it." The electric tubular lamp placed above the inner canthus and against the frontal

[1] Read before the Section on Laryngology of the New York Academy of Medicine, January 23, 1895.

[2] See *The New York Polyclinic* for February and March, 1895.

bone is only corroborative on account of the relatively frequent irregularity of the frontal cells. The character of the secretion which flows from the natural openings of the cells will indicate the diseased area with more certainty than any other subjective symptom; but on account of the usually distorted and thickened septum, and the large and irregularly formed turbinals, we are prevented from seeing the natural openings or the adjacent parts in a great number of cases. In some cases where the nares are moderately free and roomy, the diagnosis of empyema of the antrum of Highmore can be made by observing the muco-pus issuing from the outer wall, beneath the bulla ethmoidalis. A little further forward, beneath the anterior end of the middle turbinated body, where the tubal and gutter portions of the infundibulum unite, is the place where the muco-pus will appear when there is a chronic suppuration of the frontal sinus. Discharge from the most anterior of the ethmoid cells will occasionally follow the latter course. The other anterior ethmoidal cells will discharge their secretions from the median side of the bulla ethmoidalis, nearly one-fourth of an inch from any of the points where pus from the other three compartments is likely to find exit. The posterior ethmoidal cells drain through the superior meatus downward over the posterior part of the middle turbinal. The sphenoidal cells discharge their contents from an opening in the upper part of their anterior walls, very near the septum, and above the superior turbinated bodies. Since the openings of the antrums, and the sphenoidal cells, are in the upper part of their walls, it is necessary to bend downward the head in order to obtain the greatest flow. In each suspected case, where the diagnosis cannot be made from an orificial discharge or other symptoms, or by transillumination, irrigation should be resorted to either through the normal opening with the syringe and curved tube, or with the trocar and cannula passed through the wall in the middle or inferior meatus, and in an extreme case through the canine fossa. When we have determined that the cavity is the source of a mucous, muco-purulent, or purulent secretion, the question arises: Can we acquire, from the character of the discharge, a reasonable conception of the pathological condition within the cavity? Combined with the history, I believe that usually we can. This is important because it indicates the line of treatment. Other things being equal, irrigation through the natural opening should be tried in nearly all cases for a while, and be persisted in for a few months in those cases where the returned fluid contains decaying, cheesy, mucoid masses, and which show rapid improvement in the symptoms. On the other hand, when the irrigation fluid returns on succeeding occasions, laden with mealy, offensive pus, it is wiser to make an opening at once, 8 or 10 millimetres in diameter, through the malar ridge where the tip of the first molar os is situated. In the event of the first molar tooth being in place, the canine fossa would be the next point of election. In those cases where we cannot enter the normal openings, and when we are not permitted to puncture with the needle or trocar, we can frequently succeed in making a reliable diagnosis by patient and repeated examinations anteriorly and posteriorly, by removing obstructing tissues, and by tying down the soft palate in certain cases, until all spasm is relieved, or (as in Case 25) reach a decision by exclusion.

The most peculiar circumstance about cases of chronic antrum empyema is that the patients seldom complain of pain in the region of the superior maxillary bone. When it exists, which is only occasionally, it is referred to the supra-orbital, temporal, or post-occipital region. In cases of chronic disease of the frontal sinus, pain is almost invariably present, and is increased by bending the head downward. In ethmoidal and sphenoidal disease a dull pain is usually located deeply beneath the bone through the deep temporal and occipital regions. There is a class of cell diseases which we might place under the heading of acute or subacute sinusitis, with little or no stenosis of the natural opening, which improves or gets well during the summer, and has a decided tendency to recurrence in the winter. In these cases the mucous membrane becomes thickened and corrugated, leucocytes and thick pus escape, which becomes partly solidified and undergoes degenerative changes, and acts as a nidus for fermentative and irritating collections.

Under the heading of Treatment I have considered it expedient to classify the various pathological conditions met with, and have suggested the treatment which, in my experience, has been demonstrated to be the best.

CLASSIFICATION.

I. Acute catarrhal, suppurative, and infectious sinusitis, *without* complete stenosis of the normal outlet.

II. Acute catarrhal, suppurative, and infectious sinusitis, *with* complete occlusion of the normal outlet.

III. Subacute, chronic catarrhal, and suppurative sinusitis, with moderately obstructed opening, with or without decayed puro-mucoid *débris*.

IV. Polypoid degenerations.
V. Odontic periostitis and periodontitis.
VI. Atrophic rhinitis.
VII. Tumors and foreign bodies.
VIII. Syphilis.

TREATMENT.

Class I. The cases of acute nature without stenosis are very common, and usually last from three to six weeks. They come on after the manner of an ordinary cold in the head, followed within a few days by very disagreeable feelings of fulness, oppression, and dulness; in some cases a certain amount of headache exists, and a dull feeling is present in the ears. This stage is relieved by a copious flow of muco-pus. During the course of these cases the ordinary treatment for a severe cold is the best. Most individuals who are subject to this condition have from two to four attacks during the year. The rational treatment is one of prophylaxis, which consists mainly in reducing and removing the intumescent and abnormal tissues within the nose, which should be done during the intervals of the attacks.

Class II. Acute Catarrhal, Suppurative, and Infectious Sinusitis, with Stenosis.—These cases, besides requiring the ordinary treatment, demand the evacuation of the retained secretion at once. A limited amount of a saturated solution of cocaine should be applied to the parts around the natural opening, and a persistent effort should be made to enter the cell with a tube, or, failing in this, penetration with trocar and cannula should be made use of, and the cavity should be carefully aspirated and irrigated. As soon as its patulency is restored, the patient recovers rapidly. They demand the same treatment during the intervals as that described for Class I. Cases 6 and 45 are good types of this class.

Class III. Subacute and Chronic Catarrhal and Suppurative Sinusitis, with Moderately Obstructing Stenosis, Thickened Mucosa, with or without Retained Decaying Puro-Mucoid Débris.—This class of cases is the most fruitful source of post-nasal catarrh, and is rather difficult to diagnosticate accurately. The symptoms rarely indicate the latent pathological condition sufficiently to warrant the operative procedures necessary for a proper diagnosis or treatment. Attempts should be made to irrigate these cases through the natural openings, and frequently we are rewarded with a cure or decided relief, as shown in two cases, Nos. 5 and 7. It is taken for granted that in all classes of cases any abnormal intranasal condition should be rectified. When these cases resist the irrigation treatment and are of sufficient importance, a counter-opening should be made in the cell walls and proper curettage and drainage should be carried out.

Class IV. Polypoid Degenerations.—This class furnishes by far the majority of the operative cases. Woaks, Bosworth, Casselberry, and others have well described them and their treatment. Cases 2, 3, 9, 10, 11, 12, and 15 of my series typically illustrate this class. Large counter-openings, packing, careful and repeated curetting, good drainage and irrigation, are essentials for successful treatment.

Class V. Odontic Periostitis and Periodontitis, Sometimes Terminating in Caries and Necrosis.—It is universally conceded that the offending tooth in this class of cases should be removed, and, if the case is of long standing, the cavity should be opened, carefully curetted, and dressed. Formerly, following the advice of many dentists and surgeons, after the tooth had been extracted I drilled upward through the socket; but the after-history of such cases has caused me to regret it, Cases 3 and 4 being unfortunate examples. The principal objectionable features are: the distance through the bone to the floor of the antrum; the dense, thick tissue of the gum; the difficulty experienced in curetting, the long walls of the opening preventing the proper play of the handle of the curette; the easy entrance of food into the antrum, and the necessity, while eating, of plugging the tube when one is worn for drainage. I take it for granted that every one would prefer the lower border of the malar ridge for penetration in all cases where the tooth has been absent for some time. You will find this point of election marked on the skull which I pass around. The most serious obstacle which I have met with is the decided objection of the patient to losing a tooth.

In nearly all extensively diseased cases, where some other operation was performed in place of the one through the malar ridge, the patient and myself have both had cause to regret it. On the other hand, all of the worst types of cases have done well when the operation was properly performed through the point of election. The surgeon has complete subsequent control of the antrum, and can keep it open and curette it at any time without inconvenience to himself and with very little pain or annoyance to the patient. The canine fossa, where the bone is very thin, is the next point of preference; the main disadvantages are its distance up under the cheek and the elevation of the opening above the floor of the antrum.

The results in the cases where I penetrated

through the walls of the meatus have not been so satisfactory as those reported by Grant and other European writers. I have noticed that many cases, under careful and thorough curetting, ultimately did better than those which were extensively or over-curetted, or those in which the curette was used too moderately. I have found the greatest benefit from recuretting, at intervals of about one month, until all bare bone is covered and granulation tissue cicatrized.

Class VI. Atrophic Rhinitis.—The bacilli of atrophic rhinitis frequently find a permanent home in the sinuses. Robertson, of Newcastle-on-the-Tyne, has done some original and efficient work in this class of cases. I have found two kinds of cases apparently caused by this affection: one in which the semi-solid putrid *débris* has become confined in the cavity, and acts as a causal factor in keeping up the diseased condition; and the other in which the tissues have undergone degenerative changes. Irrigation will frequently relieve the first; curetting and drainage would be necessary to restore the latter.

Class VII. Tumors.—Tumors occasionally develop within these cavities. Early diagnosis is of the greatest importance, for it frequently enables the surgeon to save the patient's life by timely removal, and rescues him from a condition of intense pain and distress. Among the benign tumors, mucoceles and osteomata are the most important. The mucoceles usually develop in the ethmoidal cells, and extend antero-posteriorly through the long diameter. This is accounted for by the intercellular walls offering the least resistance. They generally extend backwards, breaking down all the partition walls and finally reaching the posterior wall of the sphenoid cells. At the same time they extend forward into the frontal sinus or against the orbital plate, cracking and pushing the same above the inner canthus of the eye. If these cases could be recognized by the symptoms and by intranasal inspection, there would be more credit for the rhinologist and less opportunity for the oculist to puncture the protruding sac.

Among the malignant tumors, sarcoma (long- and round-celled) and osteo-sarcoma are the most common. Cases 31 and 34, which belong to this class, are worthy of note. The prompt removal of the superior maxilla in Case 34 has apparently cured him of an otherwise fatal disease. Case 31 was considered inoperable, and died a few months afterward. The toxins of erysipelas and the bacillus prodigiosus modified the patient's symptoms favorably for a time.

Class VIII. Syphilis.—Gummata frequently develop in the walls of one of the accessory sinuses. I have now under observation three cases of gumma of the internal wall of the antrum of Highmore. They are doing well under the iodide of potassium and occasional scraping of the necrosed bone. The openings into the cavities are about one-half of an inch in diameter, and quantities of sticky muco-pus escape. This is gradually lessening under cleanliness and irrigation.

There are a few points concerning the treatment of these cases to which I would like to direct your special attention:

1. That no case of long-standing and extensively diseased area can be considered cured within a few months after the operation. The aperture should be kept open for from six months to a year.

2. The electric light not only indicates the direction to be followed in the investigation, but also furnishes the courage and desire to ascertain the condition of the cell.

3. The malleable-handle curettes are very valuable when used as diagnostic or searching probes. One can learn to make out the pathological condition of the cells through a trained and experienced touch about as well as when the parts are seen.

4. The headed rubber tubes, made by Meyrowitz, have proved to be the most effective and pleasant means of drainage. They can be cut to any length, and are elastic enough not to irritate the gum and cheek.

I append the histories of some of my series of cases, trusting that you will take warning from the negative or ineffectual action in the unfortunate ones, and that you will be able to obtain some useful information from those that were successful.

Case 25 stated November 29, 1893, that he had had bronchial trouble all his life, annoyed by a profuse discharge of mucus from the nose and pharynx for years, and troubled with coughs, and a copious discharge from the bronchial tubes, with one bronchial hemorrhage in September.

Both ethmoidal regions were filled with polypi, and muco-pus issuing from both hiati and ethmoidal cells. The electric light produced a dark umbra beneath both eyes.

Removed polypi and the anterior ends of the middle turbinated bones, and irrigated the antrums for several months. The patient gradually improved, bronchitis almost disappeared, and there was but little mucus in the nostrils. He gained about 25 pounds in weight, and showed decided improvement in every respect.

Case 26, aged 51, informed me in May, 1893, that he had tried many physicians and remedies

without any relief. A muco-purulent secretion dropped incessantly into the rhino-pharynx. At times this was yellow, and on rare occasions was blown from the anterior nares. His vision became very dim every morning, and there was slight tinnitus and impaired hearing. For years he had sought climatic relief from his catarrh. Three winters were passed in southern countries or on his yacht in southern seas, and the summers in northern and mountainous regions, the only relief being an occasional abatement of the extremely disagreeable catarrhal discharges.

After a long and careful examination, found the nose large and deep in both directions; septum slightly deflected; the turbinals bulged toward the septum; a few small polypi in the right middle meatus, but the nose was free from all secretion so far as anterior inspection could detect. There was a constant stream of muco-pus flowing down into the pharynx on either side of the soft palate near the Eustachian tubes, and he expectorated every few minutes. Transillumination produced a decided umbra beneath the left eye; with but a very slight translucency below the right inferior eyelid. I could not enter either antrum through its hiatus, although I tried many times on different occasions. It was a long time before I could train the soft palate to drop low enough so that I could see the posterior tips of the inferior turbinals. I could then detect the muco-pus issuing beneath the outer lower parts of the posterior inferior tips, near the pterygoid plates and palate bone. I informed him that I suspected antrum trouble, but could not prove it, and offered to make an exploratory puncture, but he refused to permit it because I would not positively promise relief. I examined and treated him regularly for several weeks, and he expressed some relief after the reduction of the tissues by cautery, removal of the polypi, and energetic spraying and douching. Summer came on, and I did not see him again until the fall.

He informed me that he had consulted other specialists since he saw me, and that one of distinguished reputation advised him not to allow me to operate on him, as he did not need it. He finally consented, under pressure, to submit to the malar-ridge operation. All his teeth were in, excepting the first right upper molar, and they seemed to be in good condition. I cocainized the tissues over the right malar ridge, made the usual incision, exposed the bone and penetrated it at the point of election with the smallest-sized burr drill, propelled by a one-eighth horse-power electric motor. This was rapidly accomplished with very little pain. I passed a saturated solution of cocaine on a cotton applicator into the antrum, enlarged the opening to about four millimetres, inserted a small-sized malleable-handled curette, and with astonishment found the anterior part of the antrum smooth and in a moderately healthy condition. On passing the curette backward and downward, a soft, spongy mass was found, which proved to be nearly an ounce of large granulations, beneath which the bone was exposed and carious to the extent of more than a square inch. After enlarging the opening to eight millimetres, a quantity of muco-pus was curetted away with granulations and softened bone. I packed the cavity with iodoform gauze, and the discharge from that side stopped at once. After an interval of several weeks had elapsed I had the first molar on the left side extracted, and a similar operation to the one done on the other side was performed, and the same careful treatment carried out. After this, all discharge into the mouth stopped. The mucosa throughout this cavity was thickened to an extraordinary extent, and came away under the curette in large pieces covered with muco-pus. It seemed to be composed of hypertrophic rather than granulation tissue. Occasional pieces of soft and roughened bone were detected with the curette. The cavities were drained and irrigated for several months, and curetted at intervals. I examined him about three months ago and found that translucency under each eye was increasing. There were no lumps of mucus in the antrums when they were irrigated. Catarrh was a thing of the past. He had not been troubled with dimness of vision since the operations.

Case 27, aged 26, had been suffering for several days from severe pain and oppression in the right side of the face, with a sensation as though the face and orbital cavity would burst. Her septum was deflected with an ecchondrosis, turbinals very much swollen, and trans-illumination produced umbra under the right eye. I reduced the intumescent tissues with cocaine, and found the tissues about the right hiatus swollen and papillomatous in appearance. On introducing one of the smallest silver tubes the confined pus escaped with the irrigating fluid, which gave her immediate relief. I removed by snare a fungating papillary growth, about three millimetres in diameter, from the internal margin of the hiatus. After several irrigations at three days' intervals the cavity gradually returned to a normal condition.

Case 28, aged 27, consulted me in September, 1893. He gave a history of extreme suffering, which had existed more than twelve years. His principal symptoms were: almost unbearable headaches, nasal catarrh, constant dropping into the throat, a tickling sensation, and a great excess of sputa, chiefly from the bronchi, in the shape of large grayish and greenish lumps. He was very nervous and unsettled mentally, and did not sleep well; he was given morphine by his physicians until the habit was almost acquired, and he then resorted to the extreme use of alcoholic stimulants in order to deaden the pain.

Polypi were demonstrated in both middle meati, with muco-pus issuing from both anterior ethmoidal cells, both frontal sinuses and antrums of Highmore, and the right posterior ethmoidal cells. I removed the polypi and the left middle

turbinal, passed the smallest sized curette into the frontal sinuses and irrigated the antrums, frontal sinuses, and anterior ethmoidal cells with the silver tubes. He experienced great relief for a while, then the frontal headaches on the right side returned and were very severe.

On November 10th, under ether, I performed an improved frontal-sinus operation, as follows: After the eyebrow was shaved, a perpendicular incision was made over the centre of the right nasal bone, extended upward across the articulation of the nasal and frontal bones to the middle of the space from which the eyebrow grew on the supra-orbital ridge, a point about twelve millimetres from the median line of the skull; from thence the incision was carried outward about ten millimetres to within two millimetres of the supra-orbital notch; from there it was made, at right angles to the latter, upward about fifteen millimetres on the forehead. The blood-vessels were compressed. The bone was well exposed and the flaps retracted. An opening was chiselled into the frontal sinus by commencing about twelve millimetres to the right from the median line of the frontal bone; the point of commencing was on a level with a point about one and a half millimetres below the supra-orbital notch. The opening was enlarged to twelve millimetres in diameter. Polypi, granulation tissue, and pus were found in the cavity, which was carefully curetted. The incision above the brow was brought together with sutures, and united by first intention without any scarring. In making the opening care was taken that none but the under surface of the supra-orbital ridge was removed and that no injury was done to the superior oblique muscle. The cavity was packed with iodoform gauze for a month, after which it gradually healed. The patient has been free from discharge and pain from this sinus since the healing. The small scar is not objectionable. I subsequently opened his antrum through the malar ridge, and curetted the polypi and granulation tissue. The cell was kept open with the rubber tubes for several months. No secretion can now be detected coming from the hiatus.

In the summer of 1894 I removed the middle turbinal on the left, cut into the ethmoidal cells through the floors, and curetted them and the left frontal sinus; then I irrigated the left frontal sinus, left antrum, and left ethmoidal cells. The discharges were nearly all arrested and he is apparently well, but it is probable that the left frontal sinus some day will need the same treatment as that employed on the right. In a recent letter he said that he felt well and could do the work of two men.

Case 29 stated, June, 1893, that for fifteen years he had been suffering from catarrhal pain and offensive discharge which had been much exaggerated for the past five years. Several operations had been performed upon his nose, but had produced no apparent relief. The odor was so extremely disgusting that one was nauseated while making the examination. I found some polypi and carious bone in the right middle meatus, with mucopurulent discharge flowing from the anterior ethmoidal cells and the antrum of Highmore. The electric light, placed in the mouth, showed a very bright illumination beneath the left eye, and an extremely dark umbra beneath the right. On June 19th the decayed roots of the two posterior molars and a part of the alveolus were removed, the cavity drilled and found full of granulation tissue, pus, carious and necrotic bone, and cheesy *débris*. When cleared it was then packed with iodoform gauze, which remained in for several days, and was afterward irrigated regularly, and lightly curetted upon several occasions. The patient seemed to be a different man from this time on. Previous to the operation he had been despondent and wretched in every way; afterward he became hopeful, cheerful, bright, and active, and entered upon new duties with energy. I received a letter from him several months after the operation, in which he informed me that he was apparently well, save a little mucous discharge, and felt himself redeemed from a life of wretchedness and uselessness.

Case 30, in April, 1894, stated that all her upper teeth had been extracted in 1891, and that immediately afterward she suffered from severe pain in the right antrum, which lasted for one week. Then pus was discharged from the right naris, with abatement of the pain. After this she was fairly well for a year; then her general health became very poor. Another abscess formed in the antrum. Her family physician drilled an opening through the alveolus, and pus flowed out. She informed me that she had adopted the novel method of wearing a rubber tube, extending from the antrum out of the corner of the mouth, until seven weeks since. About two months previous to her coming to me, the general surgeon had made a large opening through the alveolus and curetted the cavity. Inspection demonstrated a number of polypi growing from the upper, the anterior, and the lateral walls of the antrum. One large polyp grew from the bone beneath the orbit, extended through the hiatus into the nose, filled the rhino-pharynx, and rested on the soft palate. The polypi were removed with a snare and curette. New ones developed several times, but were finally eradicated. The patient is well now, and comfortable.

Case 31 applied to me in May, 1894, complaining of great pain in the right cheek under the eye, which extended back to the ear. Upon examination I found a swollen, bulging condition of the parts above the alveolus and in the canine fossa; there was absence of sensation in the integument of the cheek; the tissues of the middle meatus were edematous and semipolypoid. I made an exploratory operation through the canine fossæ; the bone was soft, and the cavity was filled

with a peculiar excrescence which seemed to penetrate the softened bone; all the symptoms were those of osteoma-sarcoma. The case was deemed inoperable because the process had extended into the ethmoidal-spenoidal bones and cribriform plate of the ethmoid. Toxins of erysipelas and the bacillus prodigiosus were tried, with some relief at first, but the patient gradually grew worse, and died after a few months. In my opinion, if the proper diagnosis had been made in the incipient stage of the disease, and the superior maxillary bone removed, she would probably have been cured; undoubtedly her life would have been prolonged many years.

Case 32, November, 1893, complained of pains and of a dull, heavy feeling in the head, weak chest, loss of voice at times, cough and expectoration in the mornings, and of a thick and copious discharge from the right nostril. He had been suffering in this way for twenty years. Upon examination the electric light produced an umbra beneath both eyes; but the shadow was much more intense under the right; a small polypus could be seen in the left middle meatus, and several polypi, with flowing muco-pus, in the right middle meatus. I removed the polypi and opened the antrum with the electric drill through the right malar ridge, the first molar tooth being absent; curetted from the cavity polypi, granulation tissue, and pus; I then packed the cavity with iodoform gauze. After a few days I removed the gauze, and gave him instructions to irrigate the cavity with the usual fluid. The last time I saw him, several weeks after the operation, he was doing very well.

Case 33, aged about 25, came under my observation several years since. She had suffered with severe headaches from childhood, from which she was seldom free; in the early morning she was troubled with sneezing, a tickling sensation in the nose, and a watery discharge, which abated about 2 P.M. The headaches were supra-orbital, and rather more severe on the right side; the septum was deflected to the left; inferior turbinates hypertrophied. I treated her for several years, reducing the turbinates and the mucous membrane over the tubercle of the septum; removed the anterior tip of the middle turbinate; cut away part of the anterior ethmoidal cells, and tried to enter the frontal sinus through the infundibulum with probes and curettes; invariably the end of the instrument seemed to be arrested by a solid substance about where the floor of the frontal sinus should be. Under ether I made a curved linear incision along the side of the nose and beneath the brow, to the supra-orbital notch; I consented, contrary to my better judgment, to drill a hole into the sinus. I drilled to the depth of four or five millimetres, until I came to a space where two layers of bone were in juxtaposition, and separated by a reddish streak presenting somewhat the same appearance as that found between geological *strata*. I decided then that if I had used the chisel the results would have been much more satisfactory to both myself and the patient, and determined to abandon the drill hereafter in this class of cases.

The patient was afterward operated upon by a general surgeon, who chiselled away the anterior wall of the frontal sinus and found a large osteoma completely filling the cavity and pressing firmly upon the walls. The patient was decidedly relieved from her headaches for a while, but I understand that they have returned with their original severity.

Case 34 was sent to me by a general surgeon in February, 1894, for my opinion concerning the right antrum of Highmore. He had been troubled with a diseased tooth, pain in the right upper jaw, and with an extremely unpleasant discharge for two years. A diseased tooth had been extracted. In August, 1892, a local dentist opened the antrum, but the pain continued. In September, 1893, Dr. Wyeth (the patient being under ether) opened and curetted the antrum through the tooth-socket, but little relief from the discharge was experienced. In January, 1894, Dr. Wyeth re-curetted the antrum, but the unfavorable symptoms continued.

In passing the curette over the antrum I noticed a thick and peculiar lining on the antrum walls, which produced very much the same sensation as one experiences when scraping a raw potato. I expressed my opinion that it was a malignant neoplasm, and, upon Dr. Wyeth's suggestion, a specimen was sent to Dr. Prudden, who reported large-celled sarcoma. In March, 1894, Dr. Wyeth removed the superior maxillary bone, with part of the pterygoid plate. The patient recovered from the operation, and seems to be doing very well with an artificial jaw, and continues in the practice of his profession as a lawyer. There remains one unfortunate result: the continuance of a constant sweetish and extremely disagreeable taste in the mouth. There is a little muco-pus issuing at the point where the section of the naso-lachrymal duct was made.

Case 35 applied to me for an opinion in May, 1894. He had consulted several specialists, and had received various opinions in regard to his trouble. Muco-pus was issuing from the right middle meatus, and seemed to be due to a burrowing empyema beneath the periosteum in the nasal wall of the antrum of Highmore, as gentle pressure with the probe along the middle meatus caused pus to flow actively. I informed him that he was suffering from empyema of the antrum, and should submit to an operation. I afterward received a letter stating that a tooth had been removed and the antrum bored into, with relief from the symptoms.

Case 36 was found suffering intense agony in the right side of her face, beneath the eye; she had not slept for many hours. Considerable tenderness existed in the canine fossæ, and I found it impossible to enter the antrum by gentle means,

as it was closed and bulging. On account of her delicate condition I did not use the exploratory trocar, but advised perfect rest, anodynes, steam inhalations of benzoin, turpentine, carbolic acid, and eucalyptol. I was rewarded in a few hours by a sudden, copious, and offensive discharge of muco-pus from the right nostril, with immediate relief from the symptoms. The patient made an uninterrupted recovery.

Case 37, in September, 1894, sought relief from a post-nasal catarrh and an unpleasant odor, which seemed to be principally on the right side, and which had troubled her for ten years. The nostrils were fairly roomy and some muco-pus was lying on the right side of the soft palate. The right antrum was dark when the electric lamp was used. I passed a tube through the hiatus, and a quantity of mucus and mealy pus was dislodged. Her physical condition would not permit a surgical operation for several months, so I irrigated the antrum four to six times a week for over a month. The discharge stopped, and she improved decidedly in feelings. She lives in a distant city, and informs me that the catarrh is returning, and that she intends to come on and have the alveolar operation performed.

Case 38, aged 48, commenced to have neuralgia at the age of thirteen in the right upper jaw, which became much worse at eighteen. The upper teeth were extracted with a part of the aveolus at this time. The pain then ceased until nine years ago. Every spring for eight years she has had very severe attacks of facial neuralgia on the right side, which last from one to three weeks. In February, 1894, the pain returned and continued up to June, and was of the most excruciating character. She consulted me at this time. She gave a history of several attacks of a copious discharge of muco-pus from the right side, attended with fulness and dulness in the antrum and severe occipital headaches.

I opened the antrum with the electric drill through the malar ridge. The bone was very soft and had an uneven surface and bulged outward against the cheek. There was a little muco-pus in the cavity, with very slight granulations and small roughened areas. The cavity was irrigated and kept open. The neuralgia ceased; the patient was comfortable and relieved until the 5th of the present month, when the pain returned with all its original intensity. On the 17th I removed the tissues which had contracted over the opening in the bone and recuretted the cavity, removing a quantity of tissue with some resemblance to an osteo-sarcomatous excrescence. The pain has ceased since the 17th, and I have sent the tissue to the microscopist for examination.

Case 39, in 1894, was suffering from nasal catarrh which was rather profuse, and with frontal headaches; his general health was impaired, and he was in a depressed condition mentally. He informed me that he had been treated by specialists for some time, one of whom removed the left middle turbinated body. After this operation he had experienced some relief from the symptoms of fulness and from the headaches, but the discharge had not lessened. There was a large cavity in the region of the middle meatus, which was caused by the absence of the middle turbinated body. I succeeded in entering the antrum through the natural opening; irrigated it at intervals of about a week for more than a month. Very offensive muco-pus was dislodged by the irrigating fluid. The patient improved decidedly for several days, and then the objectionable symptoms would recur. He refused to submit to an operation through the alveolus or the canine fossa, but I hope to induce him to do so, and will report the case at some future time.

Case 40, F. G., was referred to me by a neurologist. He had complained of the most intense neuralgia in the right side of his face for three years past. The antrum of Highmore, by every test, proved to be in a good condition; the electric light placed in the mouth produced a bright spot under the eye; no secretion flowed from the meatus, and there was nothing abnormal found in the antrum.

It was suggested that possibly some tooth-root or an exostotic condition was the cause of the neuralgia, most of which was located in the walls of the antrum, and I was requested to make an exploratory puncture. I drilled an opening, 4 millimetres in diameter, through the antrum wall at a point on the anterior part of the malar ridge, and it was interesting to note the glassy smoothness of the antrum walls. A clear and normal secretion came from the opening with the dull curette, which had been carefully passed over the internal surface of the antrum.

This is the only healthy antrum I have ever opened, and the difference in the sensation, given by the probe and the curette, is so great that it has been of the utmost assistance in determining the pathological states and areas of respective sinuses which I have opened.

The patient was partially relieved from the neuralgic symptoms—this was probably due to the section of the anterior dental nerve; and the wound healed, by first intention, in four or five days.

Case 41 in 1894 was suffering from a thick, crusty, offensive discharge from the nostril. Inspection showed a gummatous degeneration of the septum and the left internal wall of the antrum of Highmore from the hiatus downward, involving the middle part of the inferior turbinated. I removed the degenerated masses and some necrotic bone; found the left antrum filled with thick, muco-purulent tissue and *débris*. The cavity was cleansed, and curetted around the margins of the opening. The patient rapidly improved under 75 grains of potassium iodide three times daily.

Case 42 applied to me in 1894. She was suffering from such severe pains in the left side of her head that she had only slept a few minutes at a time for several nights and days. I re-

moved the gummatous wall of the left antrum; found the cavity extensively diseased and full of putrid secretion and tissue *debris*. Besides local measures I gave her iodide of potash; controlled the pain for a few days with morphine. She improved rapidly, and is now apparently well.

Case 43, aged 29, in March, 1894, had been suffering for some time from a profuse discharge in the nostrils, which was more excessive on the left. The septum was deflected to the left, and there was an ecchondrotic growth. On the convex surface muco-pus was flowing from the obscure region of the left middle meatus, and there was a moderate amount in the right nostril. He complained of severe pain in the region of the left antrum of Highmore, and also of temporal and orbital neuralgia. I removed the septum growth and the anterior end of the middle turbinated, and entered the hiatus with an irrigating tube. A quantity of degenerated pus and mucus came away with the fluid. There was a certain amount of improvement after the treatment, but the pain and muco-purulent discharge continued. He refused an operation at first, but after persistent persuasion he submitted to the malar-canine operation, which was performed on June 8, 1894. The first molar tooth was extracted and a large opening, at least ten millimetres in diameter, was chiseled into the walls of the cavity. The bone over nearly the whole surface of the antrum was not only denuded of its mucous membrane, but was carious and necrotic in many places. I curetted the cavity carefully and removed some of the largest granulations that I have ever seen come from the cell. The cavity was packed with iodoform gauze for several days; the pain subsided, and the patient improved in flesh and appearance. Granulations are gradually forming over the diseased bones, which require to be curetted occasionally. He wears a rubber tube and irrigates the cavity regularly. Pus is rarely detected in the small, thick mucous collection which passes away with the fluid. This case is classed among the severest forms, and takes from one to three years to be relieved so that the opening can be permanently closed.

Case 44. Upon examination I found him suffering with a gummatous degeneration of the septum, and a large opening in the internal wall of the antrum of Highmore, extending down nearly to the floor of the nose. There was a polyp, as large as the first joint of the thumb, protruding through this opening into the nostril. I removed the polyp, curetted away a quantity of pus and degenerated gummatous tissue, and used the usual irrigation and potash treatment. The patient made a rapid recovery, and his weight increased from fifteen to thirty pounds within a few months.

Case 45 sent for me to visit him. I found him almost in a state of collapse, and in great agony. He had been suffering for several days with intense pain together with a full feeling in the right frontal sinus. I sprayed the nostril with cocaine and applied it on cotton; found the hiatus and infundibulum very much swollen and the middle turbinated body moderately so. I passed a tube into the infundibulum and injected gently but firmly a borated solution, and was rewarded with a gush of pus and offensive gas, and with an immediate cessation of the severe symptoms. The muco-purulent discharge continued for a few weeks, but the patient recovered completely.

VERATRUM VIRIDE IN PUERPERAL ECLAMPSIA.

By F. K. WILLIS, M.D.,
of Watkins, Kan.

My object in referring briefly to this drug is in hoping to bring it to a greater prominence before the profession. Those who have used it will, I am sure, substantiate me when I say that it occupies entirely too obscure a position in our professional advancement. Why this sovereign remedy has not attained a wider reputation is, I think, due to feared depression following its use—a fear entirely unfounded. This statement is borne out by the absence of a single recorded case of death attributable to its use in eclampsia. Indeed, Periquet, quoted by Jewett, states that "he has found but a single recorded fatal case from its use, that of a feeble child, aged one year and six months, to whom thirty-five drops of the tincture had been given in divided doses."

The action of veratrum viride in eclampsia seems to be but little understood by the profession at large. It probably does not have any direct anticonvulsive properties. "Lethal doses produce convulsions in animals, doubtless due to accumulations of carbonic acid in the blood."[1]

It would seem that its beneficial action in eclampsia is twofold—its characteristic action on vascular tension and its diuretic action. There can be no doubt that it *relieves* (and I use this term advisedly) convulsions by paralyzing the vaso-motor nerves, "thus relieving spasm of cerebral vessels and consequent cerebral anemia, to which convulsions are believed to be due."[2] Were that its only action, relief would be only temporary, but it also relaxes the tension of the renal vessels, the secretion of urine occurs freely, thus eliminating the poison floating in the blood, and to this action only can be attributed its *curative* power in eclampsia. I believe all authorities concur in the opinion that eclampsia is essentially a toxemia resulting from failure of elimination of

[1] Barthalow.
[2] Percy, quoted by Jewett.

poison or poisons, principally by kidneys, but to some extent by liver, lungs, and intestines.

Experiments upon myself and office-boy show a decided increase in urinary excretion after taking small doses—3 to 5 min. fluid extract. Taking into consideration the fact that the dose was many times smaller than total dosage necessary for an eclamptic, it can readily be seen how much greater diuretic action there would be were the dose increased. This action would also be much more noticeable when renal vessels are suffering under excessive vaso-motor tension than when in health.

I shall only report in detail, briefly, two cases, both admirably illustrating its diuretic action, and incidentally its claim to rank first of all remedies in puerperal eclampsia. In each case it was used after all other resources, bleeding excepted, had failed.

Case I.—Mrs. B., primipara, aged 20 years. Had been delivered of twins, after an easy labor, twelve hours previously. I found woman comatose; pulse hard and fast, estimated at 180 per minute; great edema. I introduced a catheter and secured about an ounce of urine, which, upon boiling, yielded three-quarters its bulk of albumin. At outset she had been placed in hot bath. Morphine and chloral had been given, and chloroform was pushed. She had grown rapidly worse, coming out of one convulsion only to enter another of greater severity. In all she had about twenty-five.

I advised veratrum. Fifteen minims of the fluid extract were given hypodermatically, followed in fifteen minutes by 5 min., and that by a similar dose in half an hour. After second dose the convulsions ceased, to return no more; pulse gradually fell to 50 beats per minute; urine was passed involuntarily; edema rapidly disappeared; consciousness was regained in twelve hours, and patient made an uninterrupted recovery. It might not be amiss to here state that she has since been twice pregnant, presenting each time all the prodromata of eclampsia, which each time disappeared under veratrum, she going to term and each time giving birth to a fine boy.

Case II.—Occurred in consultation practice of my friend, Dr. Campbell, of Troy, Kan., and is by his permission reported. Mrs. G., multip., aged 29, pregnant four months. When seen by him, presented a highly edematous condition, comatose, pulse 160 per minute. Catheterization secured about half an ounce highly albuminous urine. Attending physician had pushed chloroform, morphine, and chloral. Patient had rapidly grown worse from outset. Veratrum was suggested by Dr. C. Five minims of Norwood's Tincture were given hypodermatically every hour. After second dose, pulse fell to 70 beats per minute. Convulsions ceased, kidneys resumed their function, and patient made an early recovery. Induction of labor was recommended, but not consented to at the time.

Veratrum viride not only arrests convulsions, but in several cases in my hands it has prevented them when threatened. None has suffered eclamptic convulsions who came to me complaining of headache, nervousness, presenting some edema, a full, hard pulse, etc. In this class of cases, 5 min., two or three times daily, according to urgency of case, should be given. When paroxysms occur, always administer hypodermatically 15 min. fl. ext. at once, followed in half an hour by 5 min., repeated if necessary. It may be necessary to continue administration for twenty-four hours or longer to prevent recurrence; of that the attendant must be the judge. Generally speaking, the pulse should be held at 50 or 60 for a day or two.

CLINICAL LECTURE.

THE RESULT OF VAGINAL HYSTERECTOMY; PROLAPSUS UTERI.[1]

By E. E. MONTGOMERY, M.D.,
of Philadelphia;
Professor of Clinical Gynecology in the Jefferson Medical College; Gynecologist to Jefferson and St. Joseph's Hospitals; President Philadelphia Obstetrical Society.

Case I.

Gentlemen:—One week ago I did before you a vaginal hysterectomy upon a woman who had previously had a ventro-fixation and lost an ovary. You remember we had considerable difficulty in separating the band between the fundus and the anterior abdominal wall. She did fairly well for the first forty-eight hours, when we removed the clamps. At the removal of the clamps I noticed that one of them was stained with a slight discharge of blood. But careful examination of the tissues in the vagina did not reveal any sign of bleeding. After visiting the other patients in the ward and before leaving the building, I was called to the patient and found the dressing saturated with blood. The gauze packing was removed from the vagina and the cavity thoroughly repacked, which apparently controlled the hemorrhage. She however, did badly. She could not retain nourishment, was continually vomiting, and this persisted for the next two or three days in spite of everything we could do. The gauze was removed at the end of forty-eight hours and showed that the hemorrhage had been controlled. The patient continued with disturbance of the alimentary canal and inability to retain nourishment. Yesterday morning she suddenly went into a state of collapse and died. The autopsy disclosed peritoneal inflammation. It was found that the pelvic peritonitis which had developed, in a patient enfeebled by poor nutrition prior to her entrance to the house, and the resulting hemorrhage, had

[1] Delivered at the Jefferson Hospital, January 28, 1896.

caused death. I am sorry to have had to give you such a history, but I could not otherwise be true to my promise to you. I show you the report kept of this patient, in which you see that the temperature was subnormal prior to the operation. Subsequently the highest temperature was 100⅘°, but after the removal of the clamps following the hemorrhage it fell to 97°. She, however, reacted the next day, and following that it remained above normal until just before her death. This case also taught us an important lesson regarding ventro-fixation. There has been considerable question of late as to the influence of this operation on subsequent pregnancy. Numbers of cases have been reported in which women have aborted, the uterus has ruptured, or dystocia has resulted, owing to the position of the organ. It is important in every operation upon the woman not to lose sight of its possible effect upon her life, or that of her offspring should she become pregnant. Although the operation may give relief from the symptoms the patient experiences, if it causes danger in the performance of the physiological process to which a woman may at any time be subject, we should hesitate as to its performance. I this morning did a ventro-fixation, and in the light of this experience, instead of using buried sutures, I introduced the lower two sutures through the abdominal walls, exclusive of the peritoneum, and the fundus of the uterus, purposely turning back the peritoneum to bring the covering of the uterus in contact with the muscular layer of the abdomen. This procedure will make a pretty firm band of union, but not so resisting as if buried sutures had been placed to keep the parts continuously in apposition. As the sutures only remain ten days, the adhesions become to some degree stretched and the band of union is longer and more likely to give way in subsequent stretching than would the band resulting from a more firm fixation by buried sutures.

Case II.

The next patient is 63 years of age; she has had four children, with all of which the labors were difficult. She is a laboring woman. She has noticed for the last few years a protrusion from the vulvar orifice, which has increased within the last few months. It is red, inflamed, and as I push it to one side you notice an orifice, the borders of which are denuded and angry. This is the cervix, which has been lacerated and undergone an ectropion. Now, in this patient we have a protrusion from the vulvar orifice, and you naturally ask, what is it? A woman will come to you with such a protrusion and will tell you that it is falling of the womb. It may be a growth in the vagina, a vaginal tumor, a prolapse of the uterus or of the anterior or posterior wall of the vagina. There are numbers of conditions which may cause a projection from the vulvar orifice and should be kept in mind in determining the diagnosis. In a protrusion from the orifice of the vulva, then, we remember the possibility of prolapse of the uterus, prolapse of the vaginal wall, either anterior or posterior, the anterior being known as cystocele, the posterior as a rectocele. We may have a prolapse of the entire vagina, with the cervix protruding from its center, without prolapse of the uterus, a condition known as hypertrophic elongation of the cervix, the fundus retaining its normal position. The cervix is dragged upon by the heavy vaginal walls, which results in its elongation. We may have a protrusion from the vulva of polypoid growths from the uterus, which drag upon the organ until the growth protrudes from the vagina. We may have the protrusion of the fundus of an inverted uterus; so it is important in any condition to make careful examination to ascertain the character of the protrusion, and not take for granted, because there is a protrusion, that it is a prolapsus. Prolapsus of the uterus may arise from a variety of causes. The causes may be divided into three classes: Those which result from decreased support, as in laceration of the vagina or pelvic floor, which no longer affords the proper support for the structures above, and from which the intra-abdominal pressure, having nothing to resist it, drives out the contents of the passage, causing a hernia. Secondly, we may have prolapsus as a result of increased intra-abdominal pressure, the presence of a growth which fills the abdominal cavity or rests upon the uterus, thus pushing it out. In a patient with a large amount of fat, and the abdomen greatly distended, the intra-abdominal pressure is increased, which renders the orifices less resisting, and consequently favors the tendency of the contents to escape. Third, we may have the condition arise as a result of increased weight in the organ itself; thus from subinvolution of the uterus, or growths in its walls, as the presence of a fibroid tumor. The decreased support, the increased intra-abdominal pressure, and the increased weight of the organ may all be associated in the same individual. Taking the first cause into consideration, we can readily understand if we have a laceration of the pelvic floor which extends back to the sphincter ani, or to one side of the sphincter, tearing through the lavator-ani muscle, the vulva stands open, the anus is pulled back, there is a consequent want of support of the anterior segment of the pelvic floor, the constantly filling bladder without support sags, and the intra-abdominal pressure drives it and the uterus toward the vulvar orifice. A portion of the bladder becomes situated below the level of the internal orifice of the urethra. This portion of the sac is consequently emptied of urine with difficulty. Some of the urine will remain unevacuated. In this sac the accumulating urine and the mucus become decomposed, producing an ammoniacal odor, and an irritating fluid which causes a localized cystitis. The salts are deposited, and if there is a small plug of mucus it affords a nucleus upon which large calculi may form. The sagging of the anterior segment of the pelvic floor is recognized as a cystocele. As the anus is dragged backward, accumulation of fecal matter in the rectum causes it unsupported to sag until it rolls out, forming a sulcus below the level of the anus. If the patient is lying upon her back, with limbs separated, and is directed to strain, you will see the eversion of the anterior and posterior vaginal walls. If the tumor is confined to one wall you can readily determine between cystocele or rectocele by the introduction of the finger. In the former the finger passes behind, in the latter in front, of the protruding tumor. In this patient the finger en-

ters the vagina behind the protruding mass, and the cervix is situated just behind and at the base of the tumor. The finger can enter the vagina some distance behind the cervix. This indicates that this is not a case of true prolapsus, but one of hypertrophic elongation of the cervix, and that the elongation is at the expense of the anterior part of the cervix.

Procidentia is complete prolapsus, and this term is only applicable to those cases in which the entire uterus is outside the vulva. That in any mass the uterus is outside the vulva can be readily determined by placing the fingers of one hand in front of, and the other behind the tumor, and press them together until we find that the uterus is below. In a case of elongation of the cervix we will find a thin, attenuated cord passing upward, which is the elongated cervix. Generally in hypertrophic elongation of the cervix we find one or the other vaginal wall remaining partially or entirely undisturbed, while the protrusion involves the other. We may have complete inversion of the vagina and still find the cervix elongated.

In a diagram which I show you, you can see the protruding cervix and the inverted vagina, and a cul-de-sac formed in the bladder, and another in the rectum, and yet the fundus of the uterus is nearly in its normal situation. You can readily understand the distress and discomfort a patient must experience, with a protrusion of the vagina as it settles lower in the pelvis, from the sensation of weight and pressure. In the patient I have just shown you, we have an abrasion of the cervical mucous membrane. This abrasion extends upon the vaginal surfaces about it. In some cases there is complete destruction of the mucous membrane, leading to ulceration. Sometimes the mass itself becomes thickened and inflamed, so that its return is attended with difficulty and occasionally is impossible. A protrusion of this kind may result in secondary inflammation of the peritoneum, which causes adhesions of the prolapsed intestines, so that fixation becomes so definite and determined that it is impossible to reduce and return the uterus to its normal situation. The condition of such a patient is exceedingly uncomfortable.

Having a prolapse or procidentia, we now come to the consideration of the method of treatment. The condition was one recognized by the ancients, and is one of the earliest female diseases described. The earlier authors upon the subject were in the habit of regarding the uterus as a sentient body which could be frightened back in its normal situation by subjecting it to nauseous odors or bringing it in contact with disagreeable animals. They were in the habit of permitting toads and frogs to be placed in contact with the uterus, allowing lizards to crawl over it, subjecting it to fumigation with unpleasant odors, to drive it back to its normal place. Emmett records the fact that a gentleman from one of the Southern States was in the habit of treating such patients among colored women by placing them in a kind of sling in which the head and upper part of the body were lower than the pelvis, and she was kept in this position for three or four weeks, and her vagina filled with a decoction of white-oak bark, which produced such an astringent effect upon the mucous membrane and walls of the vagina as to contract them and retain the organ in place. In looking over the history of the condition, we find patients were operated upon in various ways, mainly for the purpose of rendering the organ unable to escape from the vulvar orifice: thus, one introduced alternate gold and silver rings, and another did a plastic operation upon the perineum, by which the vulvar orifice was narrowed. Another placed a number of forceps on the vaginal wall, which were left in place until they sloughed, and the cicatrization following these sloughs narrowed the canal. We find a very great difference of opinion as to what supports the uterus in its normal position. One believed it to rest upon the upper part of the vagina like a cork in a bottle. Another regarded the perineum as the grand keystone of the arch; others the ligaments of the uterus as the retaining power; others the peritoneum as the structure which retained it in its normal situation. The truth lies not in any one of these, but in all of them: the maintenance of the uterus in its proper position depends upon the peritoneum, the ligaments, the proper condition of the perineum, and the relation of the vagina to the surrounding tissues. If the vaginal walls are torn during labor from their attachment to the levator-ani muscles, and have lost their muscular tissue, they gradually sag until they become heavy; and even if the uterus is retained in its normal situation by the proper muscular tone of its ligaments, we will sooner or later find an elongation of the cervix result. If the ligaments have lost their muscular tone, the uterus itself will be dragged down, and finally result in procidentia. This displacement is increased by the intra-abdominal pressure, by efforts upon the part of the individual in straining, constipation, or if she is obliged to lift heavy weights; anything which increases the intra-abdominal pressure will sooner or later promote the expulsion or displacement of the organ. With this review of the causes which conspire to maintain the uterus in its position, we come to the consideration of the treatment of displacement.

It may be divided: (1) into the restoration of the uterus to its normal place, (2) its maintenance. It is quite one thing to replace the organ, another to maintain it after it has been replaced. With the patient upon her back we grasp the uterus between the finger and thumb, and push it upward, carrying it into the vagina in the axis of the pelvic curve until it is brought to its normal situation. It may be maintained by mechanical means or surgical measures. The former comprise the various pessaries, such as recommended by Hodge (modified by various men); retroversion pessaries, the posterior bar of which passes behind the uterus into the posterior cul-de-sac of the vagina, carrying it upward; and the double-curved pessary of Gehrung; the cradle pessary of Graily Hewitt; ring, glass or rubber ball, and glass or rubber disc pessary. All have been made use of for this purpose. It is necessary that these should be of sufficient size to distend the vagina and maintain it above the vulvar orifice. The difficulty of all pessaries is that the vagina is so prolapsed and the vulvar orifice so large that the instrument, together with the uterus, is soon pushed

through. Then, again, we have various pessaries with external support—a pessary ending in a cup or ring, with rubber band attached to it, by which it is held up and which the patient wears continuously. This keeps the organ in place. But all these pessaries, whether with external or internal support, are foreign bodies and produce more or less irritation of the mucous membrane, more or less discomfort, the patient being constantly aware of their presence: so it is desirable to resort to other measures to bring about the relief of the condition and avoid the necessity of continuing mechanical means. To attain these ends, operative surgery must be evoked. The parts are restored to their normal situation, and an effort is made to bring about a normal condition. The difficulty in the various plastic operations on the vagina, whether upon the anterior or posterior or both walls, is that they narrow the vagina at its lower portion, while there is a tendency to rolling out of the uterus and constant pressure upon the newly united tissues. This keeps up until a process of ulcerative absorption results, and the organ is driven through, when the last condition becomes worse than the first. The first consideration should be to decrease the weight of the uterus. This is done by amputation of the cervix; and second, a plastic operation upon the anterior wall of the vagina. This may be adapted to a particular condition, being a denudation of a triangular, circular, or oval area, according to the amount of and the direction in which the narrowing can best be made. An operation which is frequently effective is that of Stolz, which consists in making an oval denudation and introducing a purse-string suture, which, when tied, contracts the anterior vaginal wall in every direction. The plastic operation upon the anterior must be followed immediately, at the same sitting, by the restoration of the posterior segment of the pelvic floor. This may be done in the form of the Hegar operation, in which the triangular denudation is made high up in the posterior wall of the vagina, followed by the narrowing of the vulvar orifice, or a denudation may be made, as has been suggested by Martin; in dissecting up a column on either side of the posterior wall, the edges of each column are united by sutures, and then the vulvar orifice contracted by an operation upon the perineum. Lefort suggested an operation for prolapsus which consisted in making a vertical denudation, about three-fifths inch wide, upon each the anterior and posterior walls of the vagina, and bringing these surfaces in contact by sutures, so that the raw surfaces of the one lay directly in contact with that of the other. This was reinforced by an operation upon the perineum, narrowing the vulvar orifice, upon which this column rested. I had the good fortune to perform the first operation of this kind done in Philadelphia. It resulted in a cure of the prolapsus, which had existed for a number of years. The result of the operation is a septum, which divides the vagina into two canals, and consequently is one which is only applicable to those cases in which the probability of conception has passed. As you can readily understand, it would be exceedingly unfortunate for any individual to have such a condition complicated by a subsequent pregnancy, as the band of adhesion would be sufficiently firm to render the delivery of the patient exceedingly difficult, if not dangerous.

If the uterus is turned backward, so that the intra-abdominal pressure is directed upon its fundus or posterior surface, constantly driving it down upon the newly-united surfaces, the treatment will be incomplete unless measures are taken to bring the uterus forward. The Alexander operation, shortening the round ligaments, will be found to serve a useful purpose, as the organ is held forward, and consequently in a position in which the tendency to displacement is greatly decreased. In the patient I have had before you this morning, a woman sixty-three years of age, in enfeebled health, in whom operation would be attended with more or less shock, possibly in whom there would be danger in the administration of an anesthetic, it becomes a question whether any other procedure of less danger would afford relief. An operation has been recently devised which consists in passing beneath the vaginal mucous membrane a number of circular sutures, preferably wire or silk-worm gut, the first passed just below the cervix, introducing the needle beneath the vaginal wall, carrying it as far as can be reached, bringing it out, reintroducing it at the point of exit, and so on until the vagina is encircled, bringing it out at the point through which it was introduced: a second suture is introduced about half to three-fourths inch below this, and so on until the last suture is passed above the vulvar orifice. These sutures are then drawn comparatively tight and fastened, pushing them back through the opening, so each is a completely buried suture. The result is a narrowed canal, through which it will be impossible for subsequent displacements to occur, and yet sufficiently large to favor drainage. Under the influence of cocaine these sutures may be introduced without the administration of a general anesthetic.

CLINICAL MEMORANDA.

TOXIC ERYTHEMA.

By CUTHBERT R. BARHAM, M.D.,
OF PITTSBURGH, PA.;
ATTENDING PHYSICIAN TO THE SKIN DEPARTMENT OF THE PITTSBURGH FREE DISPENSARY; CONSULTING DERMATOLOGIST TO THE ROSALIA FOUNDLING AND MATERNITY HOSPITAL.

UNDER this designation I wish to call attention to a form of erythema occurring in the course of pus formation. It is most commonly encountered in young children. Its form is usually macular or punctate, though occasionally of the papular or vesicular variety, and its course mild and of short duration, accompanied by moderate rigors, with rise of temperature and subsequent desquamation. The eruption itself is of slight importance, except in those rare cases where the subjective sensations of burning and itching are distressing to the patient.

The common form of small discrete macules of faint pink color, appearing first upon the abdomen and sides of the chest, few in number and widely distributed, are seen in the milder forms of endocarditis and empyema, tubercular abscesses, etc. In some cases of abscess of

the middle ear or of mastoid this form is seen, but usually attendant upon these conditions we find the macular eruption rapidly changing to a papular, and in the severer cases to a vesicular form, with rigors of moderate severity, headache and backache at the beginning, followed by rise of temperature. These symptoms may follow an infected wound, accidental or intentional (as in vaccination), where there is rapid formation of pus and absorption of the toxic products of the same.

The following cases will illustrate a few of the features noted above:

CASE I.—Male, aged 18 months. Had suffered from empyema. Chest had been drained, child improved, and drainage tube removed, the wound being allowed to heal. Rigors and rise of temperature developed one week after the tube was removed, followed next morning by a macular erythema over a greater part of the body. The chest was again drained, the fever subsiding and erythema disappearing the next day.

CASE II.—Male, aged 6 years. Suffering from tubercular abscess of hip-joint. The abscess had been opened, but owing to carelessness of the nurse had later not received proper attention, and was partially closed. A diffuse erythema developed, which rapidly disappeared after the abscess had been thoroughly cleansed.

CASE III.—Female, age 13 years. A punctate eruption appeared twelve hours after a rather severe headache and pain in the back; temperature rose to 102° F. The rash was located on face and chest, and later extended to the abdomen and extremities, at first macular, rapidly (within twelve hours) becoming papular in character, vesicular in places. The diagnosis of measles had been made before the writer saw the case. Improvement was followed by three exacerbations in ten days, when pus discharging through the outer ear disclosed an abscess of the middle ear. Treatment was instituted for this, and resulted in the prompt healing of the abscess and the complete disappearance of the erythema in two days; desquamation slight.

Dr. G. H. Fox (MED. NEWS, January 4, 1896) reports the following case:

Male, age 2 years. Eruption appeared one week after vaccination; became generalized after twelve hours. There was considerable redness and swelling around the pustule, but no signs of injury or external irritation. Eruption began to fade on the third day.

In all except the last of these cases the absorption of some toxic product of the existing inflammation was evidently the main etiological factor, since removal of the pus resulted in the disappearance of the eruption, no local application or other treatment of the eruption having been employed. In the last case both local treatment and a laxative were employed.

Dr. Fox touches lightly upon the etiology in his report, from which I quote as follows:

"These eruptions (*seen after vaccination*) may depend upon some abnormal condition of the patient, in which case the vaccination cannot be regarded as the prime cause of the rash, inasmuch as it merely evokes an eruption which was already latent, and might have appeared spontaneously, or from any one of a variety of causes."

This I consider a misleading use of the word *latent*, inasmuch as many diseases, eczema for instance, may be due to a variety of causes; yet it behooves the physician to seek the exciting cause in each separate case.

Again: "Frequently, however, the vaccinated subject is in normal health, and the vaccinal eruption, like a drug rash, can only be attributed to idiosyncrasy."

The symptoms noted—headache, malaise, febrile reaction, etc.—indicate that these cases should come under that class designated "erythema scarlatiniform." The phenomena are due to the action of some poison on the nervous system, frequently, as in these cases, the toxins produced at the foci of suppuration. The erythema is only a part of the general process, representing the action of these toxins on the vaso-motor centres. As in all diseases due to such causes, the intensity of the reaction depends to a certain extent upon the normal resisting power of the tissues or organs affected. To this extent we may ascribe its occurrence to idiosyncrasy. In other words, we may regard the toxin absorption as the prime or exciting cause of the rash, the lowered state of health, and consequent subnormal tone of the nervous system as secondary or contributing etiological factors.

A consideration of this class of cases and their etiology is presented, not so much on account of the skin and nervous phenomena as to call attention to a condition which may frequently lead to the diagnosis of an unsuspected pus foci.

32 WESTINGHOUSE BUILDING.

SARCOMA OF THE LARYNX—FINAL REPORT OF A CASE.

BY JOHN A. THOMPSON, M.D.,
OF CINCINNATI, OHIO.

IN the MEDICAL NEWS for October 24, 1895, I reported a case of sarcoma of the larynx, operated upon by a method radically different from that usually followed in laryngectomy. In the interest of truthful medical statistics, I wish briefly to report the further history of the case. At the time the article was written the patient had resumed work and was gaining rapidly in weight and strength. A little later he had a small abscess in the neck which discharged spontaneously through the opening where the tracheotomy tube was worn. After the inflammation and thickening had subsided, no trace of any neoplasm could be found in the tissues of the neck.

Early in November a second abscess developed near the median line, and this abscess was accompanied by a very rapid growth of a sarcomatous tumor in the connective tissue of the neck. The point of origin was at the level of the upper border of the thyroid cartilage on the right side, where the original growth had protruded above the larynx. The growth of this tumor was exceedingly rapid, and attended by a great deal of pain.

As no metastatic growths could at this time be located anywhere else in the body, a second operation was done November 15th. Drs. Oliver and Castle were present and

assisted at the operation. The patient was anesthetized by chloroform inhaled from a bit of gauze held over the opening of the tracheotomy tube. This simple method was more satisfactory than any of the more complicated appliances used for this purpose. The growth removed from the neck was about three inches in length, two inches in width, and one and a half inches in thickness. As all the usual landmarks except the anterior border of the sterno-cleido-mastoid had been destroyed at the previous operation, the dissection was necessarily tedious and difficult. The growth had apparently pushed the tissues before it so that only two important structures were involved. The facial artery and descendens noni nerve had to be cut in the removal of portions of the growth. After the large mass of the tumor was removed, it was found that the chain of lymphatic glands lying beneath it had become involved. The highest gland was three-fourths of an inch in diameter. The glands immediately below it were smaller; but after following down the chain until we had reached the sterno-clavicular junction without being able to remove all of the involved structures, the operation was completed with the knowledge that secondary developments in the lungs or mediastinum would soon follow. The growth was suppurating at the time of the operation. The amount of tissue removed from the neck was so extensive that it was impossible to entirely close the wound. Skin-flaps were formed so as to close as much of the wound as possible, and the remaining portion was packed with iodoform gauze.

The patient rallied rapidly after the operation. The wound healed with very little suppuration, and the patient was able to leave the hospital on the seventeenth day.

There was again a temporary improvement in his general condition, but this was soon followed by symptoms indicative of rapid growth of sarcoma in the lung. The patient began coughing up small masses of clotted blood which would obstruct the tracheotomy tube and require its rapid removal to prevent suffocation. He broke the tube in an attempt to remove it on the street one day while within two squares of my office, and came near suffocating before he reached the office and measures of relief could be instituted. December 17th he had a hemorrhage of bright arterial blood from the lung, and ever after that time suffered greatly from dyspnea. Masses of clotted blood were continually being coughed up, requiring immediate attention to the tube to prevent strangulation. The hemorrhages recurred at intervals of a few hours, in varying severity, and were attended by ever-increasing dyspnea. Physical examination showed a large mass in the left lung, and smaller nodules scattered elsewhere throughout both lungs. The patient finally died from apnea on the morning of December 21st.

The patient had acquired the art of talking by motion of the lips and cheeks so that he could readily carry on a conversation with those associated with him.

After the closure of the wound, made at the time of the laryngectomy, there was never any difficulty in swallowing. The patient ate all the ordinary foods with as much ease as before the beginning of the malignant growth.

MEDICAL PROGRESS.

Nasal Tuberculoma.—At a meeting of the Hungarian Society of Otologists and Laryngologists, Polyak (*Revue de Laryng., d'Otol., et de Rhinol.*, 1896, No. 4, p. 115) reported the case of a woman, 49 years old, who consulted him for an affection of the right nostril, with hemorrhage and gradual obstruction commencing six months before; later the left had become implicated.

The right nostril was completely filled by an irregular tumor, bleeding easily and resembling granulations. In the left, on the anterior part of septum, there was a tissue partly covered with dry crusts, of a dirty white color, of the size of a dollar, flattened, here and there granular, projecting but slightly, and bleeding easily. The tumor of the right nostril was immediately extirpated by means of the hot snare, and it was found that the neoplasm had its base on the right part of the septum corresponding to the lesions described on the left. Hemorrhage was slight.

The tumor consisted of fine reticular connective tissue, with fairly thick fibrous layers, and a few greatly dilated blood-vessels, but altogether it was but slightly vascular. Between the fibres there were numerous tubercles, presenting in the center traces of beginning necrosis. The cells were badly colored, and indistinct, the nuclei small, shriveled, and decomposed. The tubercles contained some very characteristic giant cells of Laughan.

The surrounding tissue was infiltrated with round and migratory cells, and a small number of tubercle bacilli were found, usually appearing in the giant cells.

This was therefore an undoubted case of tuberculosis of the nasal septum. There were no signs of tuberculosis in the lungs or elsewhere. The patient was well-nourished, without the slightest sign of cachexia, and was only troubled by this affection.

This disease presents itself in two forms: as granular ulcers, and the rare form with formation of a tumor, like the case above related. It seems that the disease attacks women especially, has a strong tendency to recurrence, but seldom leads to general tuberculosis.

In the discussion following, Irsai pointed out the importance of not confounding tuberculosis with lupus. The bacillus is identical in both affections, but the clinical symptoms are very different. In pure tuberculom, tuberculosis may also be found elsewhere; and although a tuberculoma may heal spontaneously, recurrences are very frequent, and therefore it is important to destroy all the morbid products, with lactic acid, after complete extirpation of the diseased parts.

Krepuska recalls two cases in which the nose and the ear were similarly affected at the same time. The tissue extracted from the cavity of the middle ear showed in both cases giant cells and tubercle bacilli.

V. Navratil said that secondary tuberculomata are much more frequent and are often taken for syphilomata, just as tubercular ulcers of the mouth and of the pharynx are often considered syphilitic.

Polyak concluded by saying that the facts recited show clearly the importance of a histological examination, because a simple microscopical examination of the exu-

date or of shreds is rarely sufficient, while the histological examination will determine at once if it be a neoplasm, tuberculoma, or simply a bleeding polypus. A test by bacterial cultures also might be tried, but is seldom necessary.

Albuminuria in the Sequence of Vaccination.—To determine the frequency with which vaccination is attended with the presence of albumin in the urine, PEIPER and SCHNAASE (*Berliner klinische Wochenschrift*, 1896, No. 4, p. 76) make a series of observations upon 122 infants successfully vaccinated for the first time; upon 54 children successfully revaccinated, and upon 127 military recruits. The examinations were made before the vaccination and on the first, third, seventh, and tenth days afterward. In cases in which albumin was found, subsequent examinations also were made. Of the 122 children vaccinated for the first time albuminuria was found in 7, or 5.73 per cent.; 474 examinations were made with positive results in 9, or 1.89 per cent. In none did nephritis develop. Of the 54 cases of revaccination albuminuria was found in 10, or 16.6 per cent., and among the recruits 10.63 per cent.

Ureteral Implantation into the Rectum.—KRYNSKI (*Centralblatt für Chirurgie*, 1896, No. 4, p. 73) points out that the most serious objection to implantation of the ureters into the rectum is the danger of infection of the kidneys by the contents of the bowel. To obviate this danger in cases of ectopia of the bladder, an elliptical section of the bladder-wall, including the opening of the ureters, may be removed and sutured into the wall of the rectum. If, however, the extremity of a divided ureter is to be implanted into the rectum it is recommended that upon the antero-internal aspect of the rectum, just below the sigmoid flexure, two incisions through the serous and muscular layers be made at an acute angle, the one 1 cm. long, and corresponding to the transverse axis of the bowel, the other from 2½ to 3 cm. long and directed obliquely downward and outward. The serosa and muscularis included between these incisions is dissected away, and at some distance from the angle of the wound an opening is made through the mucosa. Into this opening is introduced the obliquely divided extremity of the ureter, and the mucous membrane of the two is sutured the one to the other. The extremity of the ureter is covered with the dissected portions of serosa and muscularis, which are sutured into their original situation. Additional sutures unite the ureter and the bowel.

The Immunizing Power of the Blood Serum of Vaccinated Heifers.—As the result of an experimental investigation into the immunity conferred by vaccination and by inoculation with the blood-serum of vaccinated heifers BÉCLERE, CHAMBON and MÉNARD (*Annales de l'Institut Pasteur*, 1896, No. 1, p. 1) have reached the following conclusions: The serum of vaccinated heifers obtained at the height of the vaccinal process, that is, from ten to fifteen days after vaccination, possesses immunizing properties against vaccinal inoculation. This action is apparent early, a subcutaneous injection of a sufficient quantity of such serum immediately before vaccination by a number of subepidermic inoculations modifying profoundly or even aborting the subsequent vaccinal eruption. On the other hand the immunity consecutive to subcutaneous vaccination appears late, an injection beneath the skin of vaccinal lymph immediately or even a day or two or three days in advance of subepidermic inoculation with the same lymph in nowise modifying the appearance of the subsequent eruption. The rapidity of action of the serum of vaccinated heifers would seem to show that the immunizing properties are due to the presence of soluble substances rather than to that of micro-organisms. The immunity consecutive to subcutaneous inoculation with vaccine-lymph is developed slowly and gradually, not being complete before the eighth day, when it is sufficient to neutralize subepidermic inoculation with vaccine-lymph. The serum of vaccinated heifers injected beneath the skin of animals of the same species inoculated immediately afterward manifests its immunizing power in accordance with the dose injected, the minimal dose being relatively considerable. The immunity conferred by a dose of $\frac{1}{100}$ of the body-weight of an animal, inoculated immediately afterward, is incomplete but sufficient for practical purposes. The immunizing action of the serum of vaccinated heifers is apparent even when the subcutaneous injection does not procede but follows vaccination at an interval of 24 or 48 hours. The immunizing power of the serum of vaccinated heifers does not appear to be increased by injecting for two days previously vaccinal virus beneath the skin of the animal furnishing the serum.

THERAPEUTIC NOTES.

The Treatment of Erysipelas with Applications of Vaselin.—KOSTER (*Semaine médicale*, 1896, No. 9) has made a comparative study of the results of treatment in a large number of cases of erysipelas, in which various methods were employed, including painting with tincture of iodine, spraying with mercuric chloride, and applications of ichthyol and of simple vaselin, and found that the results with the last were quite as good as those with any other measure, as regards mortality, complications, and extension. The applications of vaselin were made twice daily and covered by gauze with a certain amount of compression.

Treatment of Hiccough by Traction of the Tongue.—At a recent meeting of the Société de Biologie, LABORDE (*Compt. Rend. Hebt. d. Séances de la Soc. de Biol.*, 1896, No. 5, p. 135) read, in the name of LÉPINE, a communication detailing the history of a young girl who had suffered for four days uninterruptedly from obstinate hiccough, which resisted all ordinary treatment. It was observed that when the child upon request extruded its tongue the hiccough ceased. Acting upon this observation the tongue was firmly withdrawn from the mouth for several minutes and upon its return it was found that the hiccough had ceased. Laborde referred also to two classes of similar character previously reported by Viaud.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed *exclusively* to THE MEDICAL NEWS will after publication be liberally paid for (accounts being rendered quarterly), or 250 reprints will be furnished instead of payment. When necessary to elucidate the text, illustrations will be engraved from drawings or photographs furnished by the author.

SATURDAY, MARCH 28, 1896.

AMATEUR SURGERY.

AT a recent meeting of the New York Academy of Medicine Dr. Robert Abbe, in discussing a paper on "Cancer of the Larynx," made use of the term "amateur surgery" in the following connection: "It is easy to remove a cancer of the tongue; it is almost impossible to prevent its recurrence. The study of the lymph channels and removal of all infected glands in a case of this character has given the subject a new impetus, and while it places a cure within the range of possibility, it at the same time removes the operation from the field of *amateur surgery*."

Although the significance of the expression would seem to be quite clear in this connection, he was taken seriously to task by a correspondent in the *Medical Record*. This criticism, however, gave Dr. Abbe the opportunity to make his meaning quite clear, and he has done so, in no uncertain way, in the last issue of the same journal.

The position is so well taken and the remarks are so timely that they are worthy of repetition: "I believe there is a considerable amount of grave surgery done to-day by practitioners whose temerity is stimulated by inflated statistics of small mortality under modern surgical practice, and whose feeling that they would like to do serious surgery is entirely unjustified by their training. Such novices in the larger field of work are rightly called amateurs. No man of mediocre talent or training should attempt operations involving grave risk to human life and obviously beyond his depth. He should confine himself within minor surgical limits."

Such limitation does not debar the young practitioner from his proper field of experience, nor does it close one's eyes to the fact that every one must have his first case in every field of surgery upon which he may enter. But the justification for this first essay must be found in proper preliminary training and a due sense of the sacredness of human life and the responsibility of the operator.

THE OPTICAL SOCIETY BILL.

A BILL is now before the New York State Legislature, whose purpose is to incorporate the "Optical Society of the State of New York for the purpose of improving and regulating the practice of Dispensing and Refracting Opticians." There is no doubt that the practice therein specified sorely needs improving and regulating, and should be brought under careful supervision. But the provisions of this bill have evidently not been considered with the care that the importance of the subject demands. In the first place, it delegates to untrained and unskilled hands a field of work that belongs to the medical profession. Nothing in ophthalmic practice is better established than the fact that eye symptoms are simply one manifestation of remote nervous, or constitutional causes, about which "dispensing and refracting opticians" have not the slightest conception, and yet, under this bill, they may legally assume the right to adapt glasses for the relief of headache, neuralgia, chorea, epilepsy, or any other of the many ills of life.

The bill incorporates a body without naming the incorporators. They may be jewelers' clerks or tinkers, opticians, or blacksmiths; as a matter of fact, one of them is reported not to be an American citizen. Moreover, all opticians, jewelers, or clerks, that are now fitting glasses or exe-

cuting prescriptions for lenses can secure certificates by simply making application and paying five dollars. But after ninety days from the passage of the bill no optician in the State, who is not a member of this society, can execute ophthalmic prescriptions for lenses or adapt glasses for the sight.

An attempt is made in the bill to restrict membership in the society by a system of examinations. But the requirements are not mentioned nor any method outlined by which they can be determined. The apparent supervision of the Board of Regents is nugatory, for they are compelled to select three out of the six men nominated for examiners by the secretary of the society.

The medical profession of the State should certainly make a determined effort to modify or suppress this bill.

BACTERIOLOGY.

THE EXISTENCE OF SPECIFIC CURATIVE SUBSTANCES IN THE BLOOD-SERUM OF TYPHOID AND CHOLERA CONVALESCENTS.

Recent studies, by Pfeiffer and Kolle, upon the specific immunizing substances developed in the blood, by an attack of typhoid fever or cholera, are of great interest, since they indicate that in these diseases nature limits disease not through the development of antitoxins, as in diphtheria and tetanus, but through the development of specific bactericidal substances. They found this opinion upon the results obtained from a long series of careful experiments.

Thus they found that if a moderate-sized platinum loopful of a virulent typhoid culture of twenty hours' growth is mixed with a cubic centimetre of sterile salt solution or bouillon, and injected into the peritoneal cavity of a young guinea-pig (300 grs.), the bacilli will be found to rapidly increase in numbers, and in the peritoneal cavity a bloody exudate will be thrown out if the disease is rapidly fatal, or a more purulent one if the disease is less acute.

Death takes place, according to the virulence of the culture and the number of bacteria injected, in from six hours to several days. In the more acute cases the bacilli continue to increase in numbers until death, while in the more chronic ones, after increasing for a number of hours, they cease to develop and gradually diminish. In either case death is due, according to Pfeiffer, to the poisons produced by the breaking up of the bacterial bodies and not to poisons excreted by them while living.

If now other animals are injected with the same quantities of bacilli, to which normal human blood serum is added in small and large amounts, it will be found that those receiving the culture, with the addition of small quantities of serum, die as those receiving no serum, while those receiving large amounts of serum are protected. Normal blood serum having, as is well known, feeble bactericidal properties. Finally, instead of normal serum, much smaller amounts of serum from those recently convalescent from typhoid fever were added to the same quantities of virulent bacilli as in the former experiments and similarly injected.

The behavior of the bacteria in the peritoneal cavity was in these very interesting. Thus, if tiny quantities of the peritoneal contents were taken after the injection of the mixture of the serum of convalescent patients and typhoid bacilli, it was found that almost immediately the bacilli began to lose their motility, and within fifteen to twenty minutes many of them showed signs of beginning degeneration. The total destruction of the bacilli soon followed.

The quick death of the bacilli was also shown by making cultures every few minutes from the peritoneal contents. Thus one loop of peritoneal fluid, removed thirty minutes after the injection, contained between four and five thousand living bacilli. The same amount thirty minutes later but five hundred, and three hours later but twenty. When sufficient serum is used all the bacilli died as a rule within sixty minutes. If the animals were killed no living typhoid bacilli were found in peritoneum, blood, or organs. If the amount of serum is too small after the bacilli have diminished somewhat in number they will again increase, and this increase will continue until the death of the animal.

This serum, which possessed such marked bactericidal effect upon the typhoid bacilli when in-

jected into the peritoneal cavity with the bacilli, was found in the test tubes to possess very feeble bactericidal power, and, indeed, by heating it to 60° C., it could be robbed of its bactericidal power in the test tube completely without diminishing to any appreciable extent its power when injected into the body.

The specific nature of this substance was shown in that, while acting so powerfully on the typhoid bacilli, it was without action on other bacilli closely allied to it biologically. The serum has in the future, therefore, a probable use for diagnostic purposes. The experiments with the serum of animals, immunized to the typhoid bacilli, gave similar results to those obtained from the serum of convalescent patients. With cholera the results obtained were almost identical.

From their experiments they conclude that the serum of typhoid and cholera patients contain substances which have a bactericidal and solvent effect in the body upon the bacteria of these diseases. These substances do not exert their effect outside of the body, where they are in an inactive state.

An antitoxin is not present in the serum. Normal human serum possesses feeble general bactericidal properties, which affect typhoid and cholera as all other bacteria, and is in no way specific. The serum from typhoid and cholera convalescents is not only in its bactericidal power from twenty to one hundred times stronger than normal serum, but is also specific, typhoid serum being bactericidal only to typhoid bacilli, and cholera serum to cholera spirilla.

This specific bactericidal substance in the blood of typhoid and cholera convalescents and immunized animals, is an added argument for the specific nature of these bacilli. The bactericidal substance in the serum of animals treated by increasing doses of the living virulent typhoid bacilli or cholera spirilla has not yet been obtained in sufficient concentration to make its use in the treatment of human disease seem advisable.

The results above summarized are of great importance if true, and they seem to be founded on very careful and repeated experiments. They indicate that we can only hope to find antitoxins, such as have been discovered in diphtheria and tetanus, in a few diseases. In the majority we must seek in other directions to find the means of prevention and cure substances. To a certain extent this is discouraging.

Their results also teach us to be cautious in using the various so-called antitoxins now put on the market for the treatment of almost all diseases due to bacteria. The majority of these substances certainly have none of the properties to which they lay claim.

William Hallock Park, M.D.

ECHOES AND NEWS.

Mr. George S. Davis, the publisher of the *Index Medicus*, has been elected a foreign member of the Hygienic Society of Paris, in recognition of his services to medical literature.

On March 21st, Governor Morton, of New York, signed Senator Nussbaum's bill, which raises the medical students' course from three to four years, but allows students who have entered colleges to be graduated under the rules in force when they matriculated.

The author of the statement that "Of the 3000 physicians in New York, only 600 are native Americans," should produce substantial evidence of its truth, or else correct a palpable error that is being widely quoted.

Toole's Theatre in London is to be torn down to make room for an addition to Charing Cross Hospital.

It is reported that Prof. W. O. Atwater, of Middletown, Conn., has recently conducted a series of valuable physiological experiments relative to the value of foods by placing his colleague, Dr. Tower, in an airtight chamber for a week at a time. It is said that thoroughly scientific methods have been employed in these investigations, and the results will therefore be regarded important.

On the 18th instant President Cleveland placed his official signature to the finding of the court-martial sentencing Medical Inspector Edward Kershner to dismissal from the U. S. Navy for violation of naval regulations.

It is reported from London that a bacteriologist named Czajikowski has discovered in the blood of patients suffering from measles a bacillus which is regarded as the probable cause of the disease.

The repetitions by numerous observers of experiments, first instituted by the Medical News, to determine the influence, if any, exercised by the X-rays upon germ life have invariably confirmed the negative results published in the issue of February 22d last.

Apropos of the wonderful penetrating powers of the cathode ray, a young lady, at a recent dinner party in New York, ventured the remark that she understood that these new cathartic rays could go through anything.

TWO Chinese M.D.'s of New York City, Dr. Jin Fuey Moy and Dr. Lee Foy Quong, declare that Long Tong is not suffering from leprosy, and have been making an effort to have him released from the leper colony on North Brothers Island. Their opinion, however, has not been confirmed by the experts that were sent to examine him, and Long Tong will be obliged to stay were he is.

THE 5-year-old son of a doctor in Monte Vista, Col., played doctor with his 2-year-old sister one day last week. He imitated the things he had seen his father do, and took a phial from a shelf and forced his sister to swallow its contents. The bottle contained morphine and the little patient died from its effects.

ELEVEN nurses composed the class which graduated March 16th from the New York Hospital Training School.

DURING the week ending at noon March 21st there were 31 deaths due to violence reported to the Registrar of Vital Statistics for New York City. The total number of deaths from all causes for the same week was 850.

THE female doctors of Chicago have organized The Medical Woman's Club, which held its first regular meeting last week.

DR. ANTONIO LAGORIO, founder and conductor of the Chicago Pasteur Institute, has been decorated by King Humbert with the cross of Chevalier of the Order of the Crown of Italy.

THE medical examining board of Ohio recently appointed by the Governor in compliance with the requirements of the new law regulating the practice of medicine, consists of three regular, one homeopathic, two eclectic, and one physio-medic practitioners. Dr. Charles A. L. Reed, of Cincinnati, has been appointed one of the representatives of the regular school upon this Board.

THE CHICAGO ACADEMY OF MEDICINE dined at the Leland Hotel, March 13, 1896. The chief feature following was a paper by Dr. Harriet G. B. Alexander, on "Training and Environments as Corrections of Degeneracy."

AN ordinance was passed by the Chicago Municipal Board March 9th, known as the ambulance ordinance. It contains a provision that every physician having a permit and displaying a badge, to be procured from the city clerk, shall have the right of way for himself and his vehicle in the streets as against all processions, persons, vehicles, or animals, when answering professional calls.

THE southwest wing of St. Luke's Hospital, 112th Street and Cathedral Heights, called the Norrie Pavilion, in honor of Gordon Norrie, treasurer of the hospital, was opened for patients last week. The pavilion contains 150 beds, and will be devoted exclusively to the male wards. It is six stories high. It is the third of the group of six buildings which will comprise the entire institution when completed.

MR. EDISON reports his discovery that crystals of calcium tungstate, spread upon white paper, fluoresce in the X-rays six times as strongly as do the films made with platinum barium cyanide first suggested for this purpose. He has been able to see moving objects through eight inches of wood. Mr. Edison further states that this fluorescence is also obtained with thin plates of mineral fluorite (a combination of fluorene and calcium), and after a short exposure to sufficiently powerful rays the plate retains the fluorescent picture for sometime.

SKIAGRAPHY continues to extend its practical application in surgery. On March 16th a piece of glass was located in a patient's hand in Waterbury, Conn., and successfully removed; two pieces of glass have been accurately located and later removed by incision from Sandow's right foot; on the 21st, a gunner, who was wounded while firing a salute on Washington's birthday, at West Point, and was still suffering so great pain in his arm and wrist that it was feared by the surgeons that amputation would be required on account of probable crushing of the bones, was gratified to learn that the skiagraph showed his bones intact. We would suggest that the X-ray be turned on Edward Krager, of West Orange, N. J., who swallowed his rubber plate of eight false teeth on the 18th instant. The teeth have not yet been located.

THE members of the Long Beach Life Saving Station are suffering with what was pronounced by many of the old seamen to be ship's fever, said to have been contracted from the crew of the schooner Mary E. Walker, which went ashore on Long Beach about ten days ago. The disease has spread among the people at East Rockaway, L. I., and adjacent villages. All fears have been allayed by the quarantine officer, who pronounced the disease an aggravated form of itch.

MEN of great longevity in the medical profession are pronouncedly in evidence of late. First Pennsylvania presented her oldest practitioner, Missouri followed, and then California. Now Michigan claims the oldest practicing physician in the person of Dr. William Sprague, of Coldwater. He is 99 years old, and has practiced in that town more than fifty years. But news comes from Glamorgan, Wales, that Dr. William Salmon, of that place, entered on his one hundred and seventh year Monday last. He is still in excellent health, though he has not driven out of doors since his hundredth year, and stopped smoking as a regular thing when he was 90, though now and then he has a cigarette and drinks port more freely than he used to do. He derives deep pleasure from the faith that he is the oldest Justice of the Peace, the oldest physician, and the oldest Freemason in the world, and Gladstone, who is young enough to be his son, sends him a birthday telegram each year, with sincere wishes for here and hereafter.

WHILE New York City may point with pride to her almost unparalleled hospitals, the magnificent appointments and facilities of which have not only aided the indigent sick but have attracted the wealthy as well, it is a

notable fact that no provision beyond the wards of the pest-house has been made for those so unfortunate as to contract certain contagious diseases. The evident demands of the situation have recently attracted the attention of the charitable ladies of the city, prominent among whom should be mentioned Mrs. John W. Minturn. One hundred thousand dollars was considered to be necessary for the proposed hospital, and Mrs. Minturn, herself giving twenty-five thousand, has been able to get nearly the requisite sum. Twenty thousand dollars is still needed for furnishing the hospital throughout, and it is hoped that donations for this purpose will come. It is hoped that a few of the rooms may be endowed, so that they may be occupied free of charge by those whose means would be overtaxed by the regular payment, and whom it would be absolutely cruel to send to the public wards of the Willard Parker. To endow a room requires $6000. The site selected for the building is on the public land on Sixteenth street, near Avenue C, which has every advantage of isolation, and, fronting on the broad East River, receives pure fresh air from the water. Not only will it be as germproof and fireproof as modern science can make it, but every precaution for preserving the health of the servants, officers, and those in any way connected with it will be taken.

For several weeks, what would have been an amusing controversy had it not seriously involved the welfare of members of the most unfortunate class of humanity—the mentally diseased—has been in daily evidence between the New York State Commission in Lunacy and the Commissioners of Charities of New York City. A provision for the admission of any patient to the State hospitals is that he shall be dressed in a new suit of clothes; and a failure on the part of the City Charities to provide this for those patients transferred from Bellevue has been met by a refusal to receive them on Ward's Island. After resorts to various strategies by both parties, during which, in one instance, a lunatic was allowed to escape, a truce has now been effected, pending the decision of the State courts.

Dr. Jose Manuel Delgado, a citizen of the United States residing in Cuba, has been severely wounded by the Spanish troops under General Melquiz. Although he protested that both he and his father were American citizens, the employees on the Delgado plantation to the number of eight were killed, and Dr. Delgado was bound, shot, and left by the Spaniards for dead. The matter has been placed in the hands of the U. S. Consul-general at Havana, to which place Dr. Delgado has been transported upon a stretcher.

CORRESPONDENCE.

THE TOXIC PROPERTIES OF PIPERAZINE.

To the Editor of The Medical News:

Concerning the Clinical Memorandum "Toxic Symptoms Produced by Piperazine," in the current number of the Medical News, it may be of interest to your readers to call attention to the fact that in the *Therapeutic Gazette* for January, 1893, and February, 1894, in a study of the effects of piperazine on the urine, I speak of certain untoward effects observed by myself in using large doses of the drug. In one case, to ascertain the limit of tolerance and the effects of very large doses on certain of the urinary ingredients, I gave to a woman of 150 pounds, on thirteen consecutive days, 670 grains. This dosage was given as follows: In one period of four consecutive days 70 grains were given daily in three doses. This had been preceded by 20 grains the first day, 40 grains the second, and 60 grains the third, each in three doses. The 70-grain doses were followed by 25 grains daily for two days, and these in turn again by 70 grains daily for three more days. In this case scarcely any untoward effects occurred at this time; but with a different make of piperazine untoward effects of decided nature occurred the day succeeding the one on which three doses of 23 grains each (approximately 70 grains in all) were given. This maximum dose of the new preparation had been preceded by the use of 25 grains daily for a few days.

In a second case, an adult male, weight 130 pounds, in more feeble health, toxic symptoms succeeded 70 grains daily for two days, preceded by 30 grains in three doses the first day. The toxic symptoms were of the nature of nervousness and dread, succeeded by hallucinations, coarse tremors, and these by muscular weakness in-coordination and intermittent clonic spasm. In one of these cases a stupid condition occurred, of several days' duration. In the other an attack of acute mania, lasting several days, followed the other symptoms mentioned.

I have used piperazine a great deal—perhaps more than any one in this country—and have never observed toxic symptoms of any sort from a moderate dose, as of a half-drachm daily, although the drug has been continued for long periods of time. The limit of tolerance seems to be about a drachm daily. I have never had untoward effects to occur from a single dose of 20 grains, although I have not infrequently administered it, not, however, as an initial dose. I found, in my experiments, that the two different makes of basic piperazine on the market (neither of which, by the way, is Merck's) differed from each other quite markedly in degree of toxicity. Both makes were used in my cases. This difference was ascertained to be due to a matter of concentration of the drug in the more toxic, *i.e.*, to a much smaller amount of water of crystallization. It is on account of this that a stable salt of piperazine is preferable for administration to the basic piperazine still so much used.

Very truly yours,

D. D. Stewart, M.D.

108 South 17th Street, Philadelphia.
March 17, 1896.

GONORRHŒA OF THE RECTUM.

To the Editor of The Medical News.

Dear Sir: In your issue of March 7th I notice a very interesting clinical report by Dr. J. A. Murray, of Clearfield, Pa., on rectal gonorrhœa. On the same subject in the Feb. 20th number of the *Deutsche med. Wochenschrift* is an article by Dr. Theodore Barr, assistant on the Dermatological Division of the City Hospital at Frankfort-on-Main. He gives some startling figures as

to the frequency of the disease when carefully sought for. He says that from June 15, 1895, to Jan. 1, 1896, of 191 female patients with gonorrhœa, 67, or 35.1 per cent., of all the cases had also gonorrhœa of the rectum, as was established by microscopical examination. He thinks that the supposed rarity of the disease is owing to the fact that few cases give rise to symptoms pointing to the rectum. Few have bloody or purulent discharge from the rectum, and few have pain or tenesmus. Where these symptoms are present he thinks them due to excoriations and ulcerations at the anus.

His conclusions as to the causation are also interesting, in view of the case reported by Dr. Murray. Dr. Barr thinks that the cause is almost always found in a cervical or vaginal gonorrhœa, the secretions from which are carried into the rectum by the syringe nozzle, the thermometer, or other manipulation about the anus by patients of not too cleanly habits. One of his cases developed a periproctitis as a complication, which afterward formed a fistula, in the discharge of which the gonococci were demonstrated. My attention was called to this by the two articles happening to arrive on the same day; and also by the strikingly different conclusions as to the frequency of this disease.

Yours respectfully,

Wallace Johnson.

Washington, D. C.,
March 9, 1896.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

General Meeting, March 5, 1896.

Joseph D. Bryant, M.D., President.

PNEUMONIA AS A COMPLICATION OF DIPHTHERIA IN CHILDREN.

Dr. Henry W. Berg read a paper with this title. He said that the very large number of deaths from pneumonia complicating diphtheria, in the Willard Parker Hospital, had detracted from the brilliant results of the antitoxin treatment. The records of this hospital seemed to show that the antitoxin treatment had enabled even severe cases of diphtheria to survive for a longer time than formerly after the development of a pneumonia. This grave complication was liable to appear at any time while the Loeffler bacilli were still present in the throat. The pneumonia was either the result of a direct extension of the disease by continuity into the lung, or was due to mixed infection. In the latter variety, the streptococcus played a prominent part. While broncho-pneumonia was by far the most frequent form of lung complication in cases of diphtheria, there might be a lobar pneumonia, or a gangrene of the lung, or simply a pulmonary congestion. Gangrene of the lung was apt to result from the formation of the large pulmonary infarctions seen in connection with diphtheria. As regards the symptomatology, it should be recalled that diphtheria of the larynx often runs its course without marked fever, and hence that a sudden and decided pyrexia was probably indicative of a complicating pneumonia. If, in addition to this, the respirations became very rapid, and there were fine crepitant râles to be heard on deep inspiration, or when the child cried, it might be confidently assumed that pneumonia was present. The sudden fever and rapid respiration alone would furnish a good reason for making a diagnosis of pneumonia, even before the physical signs of pneumonic consolidation were distinct. This was an important point, for when there is disseminated pneumonia, or the pneumonic process starts in the deep portions of the lung, the physical signs are often at first uncertain. By frequent and careful physical examinations one could usually determine if the pneumonia were due to direct extension of the diphtheritic process—a matter of no small importance in prognosis, for this variety of pneumonia was of very grave import. The prognosis rested chiefly on three factors, viz.: (1) The virulence of the diphtheria; (2) the stage of the disease; and (3) whether or not it was an operative case.

Regarding the matter of treatment, the reader of the paper said that he felt convinced that cases of diphtheria complicated by pneumonia should be separated from other cases of diphtheria; indeed, he believed that it was better to isolate all cases of pneumonia. The sick room should be kept at a temperature of not over 70° F., and should be well ventilated. Cases of intubation and tracheotomy should be most carefully guarded from contact with cases suffering from broncho-pneumonia. Antiseptic inhalations were useless; antipyretic drugs should be avoided, and instead the cold pack should be employed. This not only reduced the fever, but stimulated the patient. In the early stages, where antipyretic treatment was indicated, he favored the frequent application of ice-cold compresses to the chest. The use of diphtheria antitoxin in extra large doses was to be recommended in broncho-pneumonia complicating diphtheria. If the new anti-streptococcus serum proved equal to the claims made for it, we would have in this new agent a remedy which would be chiefly used to prevent such complications of diphtheria as broncho-pneumonia, while the diphtheria antitoxin would be employed to combat the toxins of diphtheria. The Board of Health of New York city is now working in this new field, and it was expected that before long some of this new anti-streptococcus serum would be at the disposal of clinicians.

Dr. H. M. Biggs said that it was now pretty generally known that with the exception of lobar pneumonia, which might be due to Fraenkel's pneumococcus, the other varieties of pneumonia were not specific infections, but resulted from the action of a variety of micro-organisms. In his opinion, the frequency of pneumonia as a complication of diphtheria was to be explained by the fact that the lowered powers of resistance of the human organism due to the diphtheria made the individual an easy prey to germ infection. It was because of the depressing effect of "hospitalism" that pneumonia was a more frequent complication of diphtheria in hospitals than in private practice. In hospital practice, he considered it advisable, though by no means essential, to isolate cases of pneumonia. He heartily agreed with the author of the paper regarding the inutility of antiseptic inhalations, particu-

larly the use of steam. This method of treatment could hardly fail to be very depressing to the patient. He favored cold as the best general antipyretic treatment, and considered that there was no contra-indication to its use except collapse. Even in cases of acute nephritis he had seen it used with benefit. Poultices he looked upon as an abomination, except in rare instances to relieve the pain of a dry pleurisy. Ice-poultices were much better.

Dr. W. H. Park said that while it might be more prudent to isolate cases of pneumonia, he had not yet become convinced that pneumonia developed in the hospital by infection of one patient by another; certain it was that repeated attempts had failed to obtain cultures of streptococci from different parts of the wards. He believed that in many instances the pneumonia, which was due to the streptococci or pneumococci, was the more important disease, and the diphtheria the complication. It has been the custom at the Willard Parker Hospital for the past two years to maintain the wards at a temperature of at least 80° F., the idea of the one who advocated it being, I believe, that as diphtheria was less prevalent in the summer, it was probably better to keep the wards at a summer temperature. A two-years' trial has proved this temperature to be detrimental, especially in laryngeal diphtheria. During the past eight weeks the effect of keeping the wards cooler, at 70° F., had been tried, and it had been already observed that there was an apparent diminution in the number of cases of pneumonia, and a lessened mortality among the young children. The former high temperature of the wards had acted unfavorably, in an indirect manner, by preventing proper ventilation. It was difficult to understand how the frequent occurrence of pneumonia during the past year in the cases of diphtheria treated in the Willard Parker Hospital could be attributed to sepsis, produced, as Dr. Winters, one of the visiting physicians of the hospital, claimed it was, by the use of diphtheria antitoxin, because the antitoxin serum is perfectly sterile. The only way in which it could be conceived to aid in the production of pneumonia was by lowering the vital resistance of the individual. As a matter of fact the proportion of cases which developed pneumonia, under the use of antitoxin, had been less than in the pre-antitoxin period. The actual number of cases had been larger because so many more had remained alive.

Dr. J. W. Brannan said that during the past year at the hospital the frequency of broncho-pneumonia in the cases of diphtheria had attracted the attention of the attending physicians. After a careful study of the subject, he had come to the conclusion that the reason so many pneumonias had been observed was that this complication of diphtheria had developed in the cases which had been saved by antitoxin. In the preceding year, sepsis had been responsible for about 30 per cent., and laryngeal stenosis for 30 per cent., but in the year just past sepsis and laryngeal stenosis together had only caused about 25 per cent. of the mortality, from which it appeared that broncho-pneumonia had been the cause of death in a large number of cases that before the use of antitoxin would have died of sepsis and laryngeal stenosis.

Three important therapeutic measures had been recently introduced at the hospital, viz.: (1) A much larger air-space had been provided for each patient; (2) the temperature of the wards had been kept down to 70° F.; and (3) elevating the foot of the bed ten inches, in order to prevent the drainage of inflecting fluids from the throat into the lower air-passages. This latter plan had been adopted at the suggestion of Dr. W. W. Seymour, of Troy.

Dr. W. P. Northrup said that in order to determine the liability of producing *schluck pneumonie* from feeding children wearing the present form of intubation tube, Dr. O'Dwyer had caused children, who were already hopelessly ill, to drink a mixture of lampblack and milk. At the autopsies on these children it had been found that in not a single instance had either the pigment or the particles of milk passed lower down than the inferior extremity of the intubation tube. He was positive that in children under 2 years of age, although the pneumonia might at times be lobar in its distribution, it was in all cases, anatomically speaking, a broncho-pneumonia. By this he meant that in these very young children with pneumonia, a very considerable part of the lesion was to be found in the bronchi. Theoretically, Dr. Seymour's suggestion about securing drainage away from the lungs was a good one, but in practice it was difficult to keep the children in proper position. Although so much had been said at this time condemnatory of the poultice, he had not felt that he could entirely dispense with it. It was the continued poulticing, and not its occasional use, that seemed to him objectionable.

Dr. William Watkins Seymour, of Troy, said that before putting into practice the method of drainage by gravity, to which allusion had been made by the preceding speakers, he had found pneumonia a frequent complication after intubation and tracheotomy. He had been surprised to see how much better his results had been since he had adopted this plan of raising the foot of the bed 16 inches. Eight out of the last ten cases intubated by him had recovered. In all these, the hot jacket or poultice had been used.

Dr. Andrew H. Smith called attention to the fact that in nearly all cases of broncho-pneumonia death results from exhaustion of the right ventricle of the heart, due to the great obstruction in the pulmonary circulation. As poorly aerated blood circulated through the lungs with much more difficulty than normal blood, it was not only important that thorough ventilation of the sickroom should be secured, but also that the patient be allowed to inhale oxygen. He had seen some very remarkable results from the early and persistent use of oxygen inhalations in this class of cases. The heart could be still further relieved by using nitroglycerin or the nitrites to dilate the blood-vessels. He was thoroughly convinced that the too common practice of using digitalis, in these cases, where the peripheral circulation was already obstructed, had been responsible for a frightful loss of life.

Dr. Achilles Rose thought that the same effect on the circulation that resulted from inhalations of oxygen could be still better attained by giving enemata of car-

bonic-acid gas, which would cause an increased interchange of oxygen in the alveoli of the lungs. This treatment by the rectal introduction of carbonic-acid gas possessed, in his opinion, much merit, although it had been hastily abandoned by most physicians because it had fallen short of the extravagant claims made for it by Bergeon and others in the cure of consumption.

CIRCULAR OF INFORMATION REGARDING THE DANGER OF CASES OF DIPHTHERIA COMMUNICATING THE DISEASE TO OTHERS AFTER CONVALESCENCE.

Bulletin of the New York Board of Health.

Diphtheria is due to a germ known as the diphtheria bacillus. This germ is present in the membrane and in the secretions of the mouth, nose, and throat of cases of diphtheria. The disease is only produced by the reception of these germs into the mouth or air-passages of other persons. The discharges from the nose and throat of cases of diphtheria containing these germs may be received on handkerchiefs, towels, bedclothing, carpets, rugs, personal clothing, toys, books, etc., dry, become pulverized, and breathed in as dust, or they may be transmitted directly from the sick to the well through personal contact, as in the use of drinking-cups or eating-utensils which have been employed by the sick, or through kissing the sick, or through the direct discharge of the secretions on the hands or face or clothing of the nurse or physician or attendant in making applications to the nose or throat of the sick person. Thus, in numerous ways the germs find their way from the throat of the sick to the mouth or air-passages of the well; and if then the conditions are favorable for the development of diphtheria in the throat of the person receiving them, after a varying period the disease is produced. Diphtheria only follows the reception of the germs in the throat if favorable conditions for their growth exist there. In many cases the germs remain for many days and increase in number in the throats of healthy persons who have been in contact with cases of diphtheria, without producing the disease. Well persons who have these germs in their throat may convey them to others who contract the disease, while they themselves escape.

During convalescence from diphtheria the germs of this disease often persist in the throat for many days after all signs of disease in the throat have disappeared, and after the individual is entirely well. Investigations show that in about thirty per cent. of cases they persist for three weeks or longer after the beginning of the disease; in fifteen per cent. for four weeks or longer; in five per cent. for five weeks, and occasionally even for a much longer time. Experiments have shown that almost invariably these germs are virulent and capable of inducing the disease in others, so long as they persist in the throat, and persons having such germs in their throats may convey the disease to well persons at any time. Observation, however, has proved that the chances of communication of the disease to well persons after complete convalescence are not great, excepting among children, who are far more susceptible to the disease and who are much more likely to become infected through the frequent introduction of articles into the mouth. The danger of communicating the disease to others after recovery is less than during the disease, because the number of germs is smaller, and because the secretions are less abundant and not likely to be discharged so that they would be received by other persons. Where persons do not remain completely isolated, as they are strongly advised to do, until cultures made from the throat show the absence of the diphtheria bacilli, they should constantly remember the facts set forth in this circular and use every precaution to prevent the communication of the disease to other persons, and should be particularly careful in their relation and contact with children.

Under no conditions will children whose throat secretions still show the presence of diphtheria bacilli be allowed to attend school of any kind, and under no conditions will adults be allowed to return to their occupation where this involves immediate contact with children.

(Signed) George B. Fowler, M.D.,
Commissioner of Health.

By order of the Board of Health,

Charles G. Wilson,
President.

Emmons Clark,
Secretary.

REGULATIONS REGARDING THE ISOLATION OF CASES OF DIPHTHERIA IN PRIVATE HOUSES.

Bulletin of the New York Board of Health.

In private houses the duration of isolation of cases of diphtheria after apparent complete convalescence of such cases shall be determined by the physician in attendance, with the following conditions:

First. Children convalescent from diphtheria shall not be allowed under any conditions to attend any kind of school—*i.e.*, day-school, Sunday-school, dancing-school, etc.—until cultures show the absence of diphtheria bacilli in the throat.

Second. Circulars of information regarding the persistence of virulent diphtheria bacilli in the throats of convalescent cases of diphtheria and the dangers from infection arising from such cases shall be furnished by the Health Department and presented by the attending physician (if the patient is a child) to the mother, father, or guardian, or, if the patient is an adult, to the patient; and the meaning of the circular and the significance of its contents explained to them.

Third. The attending physician, when continued isolation is not maintained, shall immediately notify, in writing, the Chief Inspector of Contagious Diseases, of the Health Department, of his action, and disinfection of the premises may then be performed by the Health Department.

Exceptions to this rule regarding the time of isolation of convalescent cases of diphtheria in private houses shall be:

(1) Teachers of all kinds.

(2) Persons whose occupations bring them into immediate contact with children.

The regulations of the Health Department regarding isolation of cases of diphtheria in boarding-houses, apartment-houses, hotels, and tenement-houses heretofore observed shall be continued.

(Signed) George B. Fowler, M.D.,
Commissioner of Health.

By order of the Board of Health,
Charles G. Wilson,
President.

Emmons Clark,
Secretary.

REVIEWS.

The Pathology and Treatment of Venereal Diseases. By Robert W. Taylor, M.D., Clinical Professor of Venereal Diseases at the College of Physicians and Surgeons (Columbia College), New York; Surgeon to Bellevue Hospital, and Consulting Surgeon to City (Charity) Hospital, New York. First Edition. Lea Brothers & Co., Philadelphia, 1895. One octavo volume, pp. 1002, with 230 illustrations and 7 colored plates.

It is with interest and profit that one reads Professor Taylor's exhaustive treatise on Venereal Diseases, with their complications and sequelæ. The vast amount of research which the work contains, together with the results of the author's large and carefully observed personal experience, extending as it does over a period of many years, impresses one throughout the book, as does also the broad and unprejudiced manner in which Dr. Taylor presents and reviews the many theories that have been advanced regarding the etiology, pathology, and treatment of these diseases, and the scientific and conservative conclusions which he draws. The volume, which consists of over one thousand pages, is profusely illustrated with new and clearly executed cuts and colored plates, and is divided into an Introduction and three parts.

The Introduction is devoted to the history of the three venereal diseases—gonorrhœa, syphilis, and chancroid—and shows in a clear and concise manner the etiological differences between them, at the same time reviewing the many controversies between the unicists and dualists.

The First Part, which consists of over four hundred pages, is devoted to gonorrhœa and its complications and sequelæ in the male and female, and begins with an interesting chapter on the anatomy and physiology of the penis, the urethra, the bladder, the prostate, and accessory parts.

Although the author believes that the gonococcus Neisser is the etiological factor in a large majority of cases of gonorrhœa, yet he demonstrates in a very conclusive manner that the disease may be, and sometimes is, caused by other pyogenic microbes, "the staphylococcus and the streptococcus, and perhaps others whose virulence is not yet demonstrated."

The pathology and treatment of gonorrhœa, both acute and chronic, and of stricture of the urethra, are presented in entirely new and scientific light; the author drawing his conclusions from pathological research, combined with a vast and lengthy clinical experience.

In considering the treatment of stricture, the author protests against the reckless and indiscriminate performance of internal urethrotomy for every form and variety of contraction in the penile urethra, and shows conclusively, both from an anatomical and clinical standpoint, how normal and physiological contractions are diagnosed as strictures of large calibre, and thereupon ruthlessly cut. He clearly demonstrates, by the recital of personal cases, how soft and semifibrous strictures can be cured by careful and gradual dilatation, the infiltrating cells which constitute the stricture being absorbed through the pressure and stimulation which the sound exerts, on the stenosed and thickened urethral walls. For fibrous and inodular stricture, the author advises conservative cutting, always bearing in mind the fact that the so-called calibre of the urethra is not uniform, but varies in different individuals, and in different parts of its length.

The various operations for the relief of stricture of the urethra, together with the preparation of the patient for operation, and the subsequent treatment, are most exhaustive and complete in every detail; the division of the perineal operations for bladder drainage and deep stricture clears up a part of genito-urinary surgery where there has been much confusion in nomenclature regarding these different operative procedures.

The chapters on cancer of the penis, varicocele, hydrocele, and hematocele give the reader a vast amount of valuable material in a very compact space; which may also be said of the manner in which the operations for these conditions are described.

The Second Part is given up to an exhaustive study of the chancroid, or soft chancre, and its complicating lymphangitis and adenitis. In this part Dr. Taylor modestly refers to the important clinical fact, discovered and announced in 1876 by Dr. Bumstead and himself, although independently of each other, that the chancroid has no specific virus of its own, and may, under certain circumstances, originate *de novo*.

The Third Part of the work, which is devoted exclusively to the consideration of syphilis, gives, besides the author's well-known views, everything of value that has been written on this subject up to the present time, and is therefore a storehouse of knowledge to all those interested in this disease. The nature, pathology, evolution, and course of syphilis, showing, as it does, in its early stages certain points of resemblance to the exanthemata and to diphtheria, is discussed at length and brought out in a strikingly new and interesting manner. The pathology of the chancre is most thoroughly described; the text being elucidated by numerous microscopic drawings of the initial lesion and its surrounding tissues, which clearly show the coat-sleeve arrangement of the infiltrating cells around the blood-vessels, not only those set in the chancre, but also some distance from it. From a careful study of the text and its accompanying plates, the utter futility of aborting syphilis by the excision of its initial lesion will be seen. The early and late syphilides, together with the affections of the hair, nails, and mucous

membranes, are most beautifully illustrated by half-tones and colored plates taken from the author's cases, and therefore give the reader accurate and lifelike pictures of these various affections, which are minutely described in the accompanying text.

The treatment of syphilis, beginning as it does with the abortive treatment of the disease, by the excision of its initial lesion, is the most complete and at the same time concise essay that it has been the writer's good fortune to read. The various methods and the different drugs and preparations recommended are given in detail, and their merits or demerits honestly stated; after which, the author lays down a broad line of treatment, that it will well behoove workers in this field to carefully study and follow; this treatment is ably described, is not confined to the routine use of one preparation and one mode of administration, but includes many preparations of mercury, given by the stomach, hypodermic injection, inunction, or fumigation, according to the condition of the patient and the variety of lesion that he or she may present.

When one who is familiar with the literature of these disease has carefully read and considered Dr. Taylor's work, he will lay aside the volume with the firm conviction that he has read the clearest, most unbiased, and ably presented treatise as yet published on this vast subject.

Messrs. Lea Brothers & Co., the publishers, are to be congratulated upon the general appearance of the work, which is most excellent in all respects, but especially upon the illustrations and colored plates, which show a decided superiority over those usually observed in other works devoted to this subject.

A TREATISE ON NERVOUS AND MENTAL DISEASES. By LANDON CARTER GRAY, M.D., Professor of Diseases of the Mind and Nervous System in the New York Polyclinic. New (2d) edition. In one very handsome octavo volume of 728 pages, with 172 engravings and three colored plates. Cloth, $4.75; leather, $5.75. Philadelphia: Lea Brothers & Co., publishers, 1895.

The first edition of this treatise was fully noticed in the NEWS. The fact that it has gone to a second edition in two years shows that its merits have been fully appreciated by the profession at large. The present edition has undergone a real revision, the result of which has been to greatly increase the value of the work. Additional chapters, describing different forms of insanity, have been added, the anatomical introduction has been remodelled, and the index, which in the first edition was defective, has been made all that could be desired. Some new and beautiful plates have been added, and the illustrations in the first edition have in many cases been re-executed. Cortical histology and histo-pathology, as illustrated by the work of Golgi, Cajal, and Andriesen, have received due consideration, both in the introduction and under the pathology of some of the organic forms of brain disease. The bibliography has been omitted in order to make room for what the author regards as more important new matter. The recognition by the author of the position and importance of syringomyelia is in contrast with the views expressed by him in the first edition. It is not necessary to again review in detail this work. The first edition has met with deserved success, and the present shows many improvements, both in positive additions in the text and illustrations of material of great value, and in the correction of the defects and shortcomings of the previous edition. The treatise will continue for many years to be a welcome book to the student and general practitioner. The paper and printing are of the very best quality.

AN ELEMENTARY COURSE IN EXPERIMENTAL AND ANALYTICAL CHEMISTRY. By JOHN H. LONG, M.S., Sc.D., Professor of Chemistry and Directory of the Chemical Liboratories in the Schools of Medicine and Pharmacy in the Northwestern University. Small 8vo. 497 pages and Index. Chicago: E. H. Colegrove & Co.
